Migraine is a painful and disabling headache disorder that has plagued humanity for thousands of years. Julius Caesar, England's Queen Mary, Thomas Jefferson, Claude Monet, Vincent van Gogh, Georges Seurat (visual disturbances of migraine aura, the Seurat effect), Alexander Graham Bell, Friedrich Nietzsche, Peter Tchaikovsky, and Sigmund Freud all suffered from migraine. Over the centuries, migraine has been transformed from a disease that is caused by evil spirits to a vascular and then a neurovascular disorder with well-defined epidemiology, pathology, pathophysiology, pharmacology, therapeutics, and genetics. Several thousand years BC, trepanation was a common practice used to relieve migraine by releasing demons from the head. Egyptians bound a clay crocodile, holding grain in its mouth, to the head of headache patients, using a strip of linen that bore the Gods' names. Galen considered migraine a visceral pain disorder when he said, "How constantly do we see the head attacked with pain when yellow bile is contained in the stomach: as also the pain forthwith ceasing when the bile has been vomited." (Koehn, 1826) Tenth century Arabian physicians used garlic and hot iron on temple incisions (two-site venesection) to relieve head pain.

More recently, Sir Thomas Willis believed that migraine was caused by vasodilatation, arguing that headache symptoms were related to slowly ascending spasms beginning at the peripheral ends of the nerves. Similarly, Erasmus Darwin (Charles Darwin's grandfather) believed in vasodilation-induced migraine and proposed to treat it with centrifugation in order to force the blood from the head to the feet. Edward Living commented in "On Megrim, Sick-headache, and Some Allied Disorders" that the migraine, similar to epilepsy, is a malady of the nervous system caused by nerve-storm, which may be the first account of cortical spreading depression (CSD) as an initiator of migraine. Sir William Gowers proposed dividing the treatment of headache into prophylactic and episodic. He advocated continuous treatment with drugs to render attacks less frequent and treatment of the attacks themselves. In the late 1800s, the potent neurotoxin ergot, which comes from a fungus that grows on rye, was used to treat unilateral headache. Later in the early 1900s, the active chemical ergotamine was

discovered and became the preferred treatment for migraine.

The modern understanding of migraine started with the work of Harold Wolff, a migraine sufferer himself, who performed elegant clinical experiments that supported the vascular theory of headache. Wolff and Ray published in 1940 a detailed map of pain-sensitive structures in the brain, which provided the basis for the link between arterial pathology and referred head pain. Contemporaneously, Leao discovered CSD in animals, which later was equated with human visual aura. Today, this phenomenon can be imaged and measured, and it is forming the backbone for the development of several classes of potential antimigraine drugs. To this end, it is important to mention seminal research from Boston (Cutrer and Sanchez del Rio), Detroit (Welch and Cao), Los Angeles (Woods), and elsewhere, which provided us with a window for analyzing and quantifying CSD in humans.

In the 1960s and beyond, Sicuteri, Lance, and Anthony stressed the role of serotonin in migraine. Their work was later amplified by Saxena, Humphrey, Martin, and others, who discovered the triptans. Also, the Copenhagen group led by Olesen drew attention to a mismatch between cerebral blood flow (CBF) changes and symptoms of migraine, which challenged the vasoconstriction-vasodilation theory. The same group evaluated the role of nitric oxide (NO) in inducing headache, and now NO synthase (NOS) inhibition is becoming a prime target in averting migraine.

The understanding of migraine mechanisms and therapeutics evolved over the last 2 decades with experiments that Moskowitz and fellow researchers conducted. The activation of the trigeminal system in animals was shown to induce plasma protein extravasation and neurogenic inflammation, and many antimigraine therapies blocked this response. Similarly, the initial work of Edvinsson and Goadsby was amplified in the last 10–15 years, culminating in advancing calcitonin gene-related peptide (CGRP) antagonists for migraine. Also, important work from Detroit, Michigan, and Bologna, Italy, supported the theory that the brain-energy metabolism in migraine sufferers is defective and that magnesium deficiency may contribute to the disease. These observations opened the field to testing magnesium, co-enzyme Q10 (CoQ10), and riboflavin (B2) for migraine prevention. Apropos, John Graham modernized the preventive treatment of migraine with the introduction of methysergide, Oscar Reinmuth's group drew attention to the role of propranolol in migraine, and recent studies from Welch and colleagues and Ferrari and coworkers suggested that migraine may be a progressive disorder that may warrant early and aggressive preventive therapy.

Finally, the potential role of peripheral and central sensitization in migraine, which Burstein and colleagues are unfolding, is opening new windows into migraine therapeutic strategies.

Migraine is not an orphan in the era of genomic discoveries. French and Dutch researchers led the effort demonstrating that some forms of migraine result from defective calcium trafficking across its channels and provided a new avenue for exploring migraine mechanisms and therapies. A knockin model of abnormal mutations now provides a model of familial hemiplegic migraine and susceptibility to CSD. Also, the discovery of mutations in the Na-K adenosine triphosphatase (ATPase) gene is steering us to new pathophysiological and pharmacological directions. Indeed, excessive synaptic glutamate (Glu) is a by-product of these mutations, which predisposes the migraine brain to hyperexcitability, sensitization, and/or neuronal cell death.

Epidemiology

Prevalence estimates of headaches vary significantly among studies. For example, the prevalence of headache disorders in Europe and the United States ranges from 13% (1-year prevalence in people with serious headaches) to 93% (lifetime prevalence in the United Kingdom, based on a telephone interview). Several factors contribute to the observed variability, including the time periods used for estimating prevalence (e.g., 1-year vs. lifetime), targeted age range and other sociodemographic factors, methods of ascertaining headache diagnoses, and cooccurrence of different headache types. Regardless of the study methods, the majority of population-based studies of headache disorders in adults indicate a female preponderance, which is not unexpected because most chronic pain disorders with a remitting and relapsing course (e.g., fibromyalgia and irritable bowel syndrome) are more prevalent in women.

Rasmussen et al. conducted a large 1991 epidemiological study (1000 people, 25–64 years old) on the prevalence of headache disorders in Copenhagen County, Denmark. Tension-type headache was the most common, followed by fasting headache, migraine, and headache attributed to nose or sinus disease (Table 1).

Epidemiology of Migraine

Few longitudinal studies have investigated the incidence of migraine. A 12-year follow-up of a Dutch general population sample ($n = 549$) determined that the incidence of migraine was 8.1 per 1000 person-years (male : female = 1 : 6). Data from a 2005 prevalence

Table 1 Lifetime prevalence of headache disorders in Denmark^a

Type	Prevalence (%)
Primary headache disorders	
Tension-type headache	78.0
Migraine	16.0
Secondary headache disorders	
Fasting	19.0
Nose and sinus disease	15.0
Head trauma	4.0
Nonvascular intracranial disease (e.g., brain tumor)	0.5

^aFrom Rasmussen, B. K., Jensen, R., Schroll, M., et al. (1991), Epidemiology of headache in a general population – a prevalence study, *Journal of Clinical Epidemiology* **44**, 1147–1157.

study in people 12–29 years old revealed slightly higher numbers – the incidence of migraine with aura was 14.1 per 1000 person-years and that of migraine without aura was 18.9 per 1000 person-years.

The incidence of migraine is two to three times higher in females than in males, and the peak age of onset is 5–9 years in males and 12–13 years in females for migraine with aura. For migraine without aura, the figures are 10–11 years for males and 14–17 years for females. The incidence of migraine may be increasing, particularly in women 10–49 years old.

In contrast to the paucity of studies of migraine incidence, several reports from various countries across the globe addressed migraine prevalence and established that it is a common disorder with particular predilection to Whites and women. Prior to 1988, population estimates of migraine prevalence varied from 3 to 35%. The application of the International Headache Society (IHS) 2004 diagnostic criteria led to more robust and consistent data on migraine epidemiology and allowed a better assessment of demographic influences such as race, socioeconomic status, gender, and geographical location. Indeed, several studies have now provided gender-dependent estimates of the 1-year prevalence of migraine: approximately 3–22% in women and 1–16% in men. The prevalence of migraine is highest in North America and lowest in Africa (Figure 1).

Population studies have confirmed that migraine is more prevalent in females than in males older than 12 years (female : male = 2–3 : 1), regardless of race or geographical location. Migraine in children is almost as prevalent in boys as it is in girls.

The prevalence of migraine follows an inverted-U curve with advancing age (Figure 2). This phenomenon is significantly more pronounced in females. The peak prevalence of migraine is in the fourth and fifth decades; it declines substantially thereafter.

Figure 1 Prevalence of migraine across continents. From Lipton, R. B. and Bigal, M. E. (2005), *Migraine: epidemiology, impact and risk factor for progression*, *Headache* 45(supplement 1), S3–S13.

Figure 2 Prevalence of migraine by age. From Stewart, W. F., Lipton, R. B., Celentano, D. D., et al. (1992), *Prevalence of migraine headache in the United States: relation to age, income, race, and other sociodemographic factors*, *Journal of the American Medical Association* 267, 64–69.

Migraine varies with race. Whites are more commonly affected (prevalence = 20.4% in women and 8.6% in males) than African Americans (16.2% in women and 7.2% in men) or Asian Americans (9.2% in women and 4.2% in men). Contrary to a widely held belief, migraine is more common in low-socio-economic groups and in less-educated individuals. The use of care data indicate, however, that people in higher social strata and better-educated migraine sufferers are more likely to seek medical advice.

Neural Basis of Head Pain

Triggers of head pain in different headache disorders may vary, but the substrates for pain generation, stimulus conduction through the peripheral and central nociceptive pathways, recognition and perception of the experience, and memory and reaction to pain are largely similar whether the type of headache is primary (e.g., migraine) or secondary (e.g., trauma).

Figure 3 Nociceptive and modulatory pathways. Pathways in yellow represent afferent projections subserving pain; pathways in orange represent descending, mainly inhibitory projections.

A discussion of trigger mechanisms is beyond the scope of this article, but a brief overview of the final common pathways in pain are described next.

Neuroanatomy

The pathways of head pain can be anatomically dissected into four distinct locales (**Figure 3**):

1. Sensing organs such as the skin and blood vessels.
2. Sensory-discriminative regions, which include the trigeminal nucleus caudalis (TNC), thalamus, and the primary (S1) and secondary (S2) sensory cortices.
3. Emotion, memory, and behavioral response networks. These include the insula and hippocampus, which encode the memory and recognition of pain; cingulate, which modulates the affective and motivational aspects of pain; and precentral cortex, cerebellum, and cingulate, which are involved in the reaction to the painful experience.
4. Modulatory, predominantly inhibitory regions such as the hypothalamus, basal forebrain, and various brain-stem structures.

Head pain is generated when pain-sensitive intracranial structures are stimulated. These include vascular structures such as the circle of Willis and proximal middle cerebral arteries, neuronal structures including the trigeminal and glossopharyngeal nerves, and the cranial meninges, particularly the perivascular components of the dura. Pain signals are transmitted

from these nociceptive structures cephalad, mostly via A δ and C fibers that contain neurotransmitters such as Glu, CGRP, substance P (SP), and neurokinin A (NKA). Middle meningeal artery nociceptive fibers travel through the first division of the trigeminal nerve (V1) to the ipsilateral trigeminal ganglion (TG), whereas fibers from the middle cranial fossa dura run in V3 to the ipsilateral TG. First-order neuron fibers in TG then project centrally onto secondary sensory neurons in the TNC, which in turn send their projections to the contralateral nucleus ventralis posteromedialis (VPM) of the thalamus. Projections of the nociceptive pathway from the trigeminal brain-stem nuclear complex include the trigeminal lemniscus, hypothalamic projections, pontine parabrachial nucleus (PBN), reticular formation, and the nucleus of the tractus solitarius (NTS). PBN feeds back into the trigeminal brain-stem nuclear complex and is involved in nociceptive control. Central processing of incoming pain signals beyond the thalamus include cortical areas such as the cingulate, insular, S1, and S2, as well as the cingulate gyrus and insula. Cortical neurons that are activated during head and peripheral pain include localizing and discriminating pain neuronal pools, which receive afferents from VPM, and those involved in the effective components of pain, which receive afferents from the medial thalamus.

Descending, predominantly inhibitory neuronal fibers project from the frontal lobe cortex to the hypothalamus and the periaqueductal gray (PAG) and from there descend to the rostral ventromedial medullary nuclear complex (RVM, the raphe magnus and adjacent reticular formation), which ultimately projects to the medullary and spinal dorsal horns.

Neurochemistry

The PAG–RVM system contains serotonin (5-HT) excitatory neurons that activate inhibitory interneurons of the substantia gelatinosa and lamina II of the spinal trigeminal nucleus. Electrical stimulation of either PAG or RVM or the exogenous injection of opioids, which activate the 5-HT system, results in inhibitory activity in the nociceptive neurons in the dorsal horn. Independently of PAG–RVM, a diffuse noxious inhibitory control (DNIC) system (not shown in [Figure 3](#)) directly reduces the firing of wide-dynamic range (WDR) neurons of the medullary dorsal horn cells following noxious stimulation from parts of the body that are remote from their receptor field.

The neurochemicals that are involved in pain derive from the vascular endothelium of nociceptive structures, which contains both vasoconstrictive (e.g., thromboxane, superoxide ions, and endothelin) and

vasodilator substances (e.g., NO and prostacyclin), and from the adventitia–media junction of intracranial vessels, which are rich in neuropeptide-positive terminals (e.g., CGRP and SP).

Neurophysiology

Nociceptive activation induces peripheral sensitization, which is predominantly mediated by enhanced Na channels opening. This process perpetuates discharges along the nociceptive terminals and into TG with an ongoing cycle of enhanced Na-channel opening, excitatory neurotransmitter release, and further neuronal activation. With time, peripheral sensitization, perhaps through excessive N-methyl-D-aspartate (NMDA) Glu receptor activation, leads to a central sensitizing process initially at the TNC level and subsequently at the thalamic level and beyond. The phenomenon of central sensitization manifests physiologically as spontaneous activity in otherwise quiescent neurons, reduced threshold to activation, and expansion of the neuronal receptor field following distal stimulation.

Peripheral and central sensitization could continue unless various protective neuromodulatory mechanisms become operant. Modulation is mediated peripherally through the presynaptic inhibition of neurotransmitter release or centrally through several possible mechanisms, including the inhibition of afferent input. At the peripheral level, serotonergic presynaptic receptors of the 5-HT_{1D} and 5-HT_{1F} types and some metabotropic Glu receptors participate in suppressing neurotransmitter release. Centrally, TNC neurons are inhibited by local inhibitory interneurons (e.g., GABAergic), by activation of presynaptic inhibitory receptors (5-HT_{1D}, 5-HT_{1B}, 5-HT_{1B}, and metabotropic), or by descending inhibitory fibers (e.g., noradrenergic, adenosinergic, glutamatergic, serotonergic, and GABAergic). The descending modulatory system itself is under the control of various hypothalamic–pituitary outputs, such as estrogen levels, and melatonin cycles, which have direct relevance to the roles of sleep and menstrual cycles in migraine and other painful disorders.

Genetics

The genetics of most headache disorders remain elusive. On the other hand, some major advances in the genetics of migraine have been published in the last decade or so.

There is mounting evidence that a subform of migraine (familial hemiplegic migraine, FHM) is due to a membrane ion channelopathy or ionopathy ([Table 2](#)). A net gain of function of the calcium

Table 2 Some genetic defects in familial hemiplegic migraine that might predispose to hyperexcitable neurons^a

<i>Chromosome</i>	<i>Gene mutations locale</i>	<i>Potential biological or physiological consequence</i>
19p13	CaCNA1A (Ca _v 2.1)	↑ Ca ²⁺ into presynaptic neuron, causing neurotransmitter release (e.g., glutamate)
1q23	α ₂ subunit of Na ⁺ /K ⁺ ATPase	Defective clearing of glutamate from synaptic cleft
2q24	Neuronal Na channel	Enhanced EPSP
5p13	EAAT1 glutamate transporter	Defective clearing of glutamate from synaptic cleft

^aCaCNA1A, α₁ subunit of calcium channel gene; ATPase, adenosine triphosphatase; Na, sodium; EPSP, excitatory postsynaptic synapse; EAAT1, excitatory amino acid transporter type 1.

channel leads to an excessive intracellular calcium influx into the presynaptic glutamatergic terminal, Glu release, and persistent postsynaptic activation that predisposes to cortical spreading depression (CSD). Indeed, a knockin mouse model of a CaCNA1A mutation that predisposes animals to CSD and transient hemiplegia has been developed. Alternatively, a defective Na pump reduces the efficiency of Glu transporters in clearing Glu, resulting in excessive Glu at the synaptic cleft and subsequently in continued postsynaptic excitation. Interestingly, a heterozygous mutation on the gene encoding for the Glu transporter excitatory amino acid transporter type 1 (EAAT1) was discovered in 2004 in a patient with seizures, migraine, and alternating hemiplegia. Last, hyperexcitability can be caused by a neuronal Na-channel mutation, reported in 2005.

Genetic defects in FHM might not be extrapolated to the more common forms of migraine with and without aura, especially with the absence of consistent evidence of genetic mutations or functional polymorphism at the known FHM sites, but nearby loci are implicated. Furthermore, a 2005 genomewide scan of people with common forms of migraine confirmed genetic susceptibility at sites previously reported with FHM. In addition, new susceptibility loci were reported (3q and 18p11), which deserve further exploration.

Migraine Mechanisms

The mechanisms of migraine pain and its associated neurological, gastrointestinal, and autonomic manifestations are multiple and complex. Attacks could manifest as an isolated symptom (e.g., migraine aura without headache) or a sign and symptom complex (e.g., migraine with aura), which could take on a range of phenotypic expressions (e.g., emotional lability as part of a premonitory symptom complex followed by pain or a full-blown multiphasic attack manifesting as depressive symptoms, followed by a visual aura followed by pain with nausea and photophobia and phonophobia, and terminating with social-withdrawal feelings and tiredness). Therefore, deciphering migraine mechanisms requires a

comprehensive understanding of the isolated manifestations and explanations for the event sequences.

Migraine is a neurobiological disorder of altered neuronal excitability and defective adaptive mechanisms to stressors of the system. The susceptibility to migraine is an interplay between genetic factors and environmental elements (e.g., stress and weather change). The migraine cascade can be conceptualized as a sequence of events occurring in a series, starting with the activation of hypothalamic pathways that trigger the premonitory symptoms and followed by cortical neuronal activation and CSD. Neuronal activation releases various substances such as hydrogen ions and NO, which in turn activate nociceptive terminals that, on the one hand, cause the release of substances such as CGRP and, on the other hand, transmit neuronal impulses into the medulla to the thalamus and up to the cortex for perception and reaction to the headache. CGRP, SP, and NKA participate in neurogenic vasodilation and inflammation, leading to peripheral sensitization and an abnormal response to previously innocuous stimuli (e.g., blood-vessel pulsations becoming painful). Often, peripheral sensitization can culminate in central sensitization with the activation of ancillary trigeminal nociceptive (e.g., allodynia in the distribution of the first division of the trigeminal nerve) and paratrigeminal pathways (e.g., photophobia and phonophobia).

The female preponderance of migraine sufferers provides some insight into the mechanisms of headache and pain. A discussion of the role of sex hormones and migraine mechanisms is quite complex and beyond the scope of this article, but a few highlights are noteworthy. Women detect trigeminal pain at a lower threshold than men, and their tolerance for the painful stimulus may be lower. Some researchers observed that these gender differences may be related to higher sensory-receptor density on the peripheral nerve terminals in women. Furthermore, estrogen receptors (ERs) are distributed on various neuronal pools that participate in migraine pain trafficking (e.g., TNC, hypothalamus, amygdala, PBN, and PAG). Lastly, ERs modulate neuropeptides in the trigeminal system that are involved in migraine (e.g., CGRP, SP, and NKA).

Table 3 Comorbidity of migraine and systemic and psychiatric disorders

System	Condition
Gastrointestinal	Irritable bowel syndrome
Neurological	Epilepsy
	Multiple sclerosis
Psychiatric	Affective disorders
	Anxiety disorders
	Neuroticism
	Sleep disorders
	Substance abuse
	Suicide
Pulmonary	Asthma
Vascular and cardiovascular	Hypertension
	Hypotension
	Ischemic stroke
	Myocardial infarction
Others	Allergies
	Raynaud's phenomenon

Migraine is comorbid with psychiatric conditions such as generalized anxiety disorders and depression (Table 3), and migraine attacks often are triggered by stress and lack of sleep. It has been suggested that bidirectional signal transmission through the trigemino-vascular system accounts for both the migraine symptoms and the induction of these symptoms by triggers such as stress. Also, migraine shares similar mechanisms with chronic pain when comorbid psychiatric conditions such as depression could result from functional alterations in the reward-aversion pathways.

Migraine patients have some personality traits such as neuroticism, which could lead to altered coping mechanisms. Indeed, one study suggested that a migraine sufferer's coping mechanisms include amplified physical symptoms, social litigation, and preoccupation with stress. Also, migraine patients are less calm, more irritable, do not relax as well as a nonmigraine healthy controls, and often respond to physical symptoms, including pain, with internal tension.

Classification of Headache Disorders

The development of a headache disorder classification that is intuitive, psychometrically robust, and easy-to-use enables a better understanding of conditions associated with headache, improves patients' management, and provides a standardized approach to headache research. Headache disorders can be classified broadly as primary (e.g., migraine), and secondary (e.g., posttraumatic). Indeed, the *International Classification for Headache Disorders* (2nd edn.;

ICHD-II) recognizes this dichotomy (Table 4). Primary headaches are classified largely on the basis of symptoms, whereas secondary headaches are grouped etiologically. Both acute and chronic forms of primary and secondary headache disorders are recognized (e.g., chronic migraine and chronic posttraumatic headache).

Clinical Presentations and Differential Diagnosis of Migraine

Migraine is characterized by episodes of head pain that is aggravated by movement, with associated nausea, photophobia, and phonophobia. Head pain in migraine is unilateral in approximately 60% of patients and throbbing in many but not all. Up to one-third of migraine patients experience transient neurological symptoms (i.e., aura) that herald or accompany the pain. Most migraine attacks last approximately 1 day (4–72 h in adults; they are of shorter duration in children), and their frequency is quite variable. The frequency of migraine is approximately once per month in population-based studies and three times per month in clinic-based cohorts. In the general population, 2–3% suffer chronic migraine, which is defined as attacks that recur more than 15 times per month. Last, the majority of migraine sufferers are disabled with their attacks.

A careful history and appropriate physical and neurological examination establish most causes of headache disorders. For example, the presence of associated symptoms (e.g., nausea and photophobia) helps to differentiate migraine from tension headache. Important elements of the history that help in establishing the diagnosis include (1) age of onset; (2) duration; (3) time to peak severity; (4) severity and headache-related disability; (5) frequency; (6) location; (7) preceding and accompanying symptoms, if any; (8) precipitating and aggravating factors; (9) circadian or diurnal patterns; and (10) relieving factors. It is also crucial to obtain a full headache medication history, including over-the-counter remedies.

The clinical presentations of migraine with and without aura are often characteristic (Table 5). On the other hand, the clinical presentations of secondary headache types mimicking migraine with aura are not unique (Table 6), with a few exceptions (e.g., benign or idiopathic intracranial hypotension). Also, the symptom complex of migraine and that of other primary headaches and secondary headaches overlap (Table 7). An algorithm that helps in the differentiation between primary and secondary headache disorders uses red flags (called SSNOOPs, an acronym based on the first letter of items in the

Table 4 Second International Classification for Headache Disorders (ICHD-II)^a

Category	Type
Primary headache disorders (categories 1–4)	Migraine, tension-type headache, cluster headache and other trigeminal cephalgias, other primary headache (e.g., primary stabbing headache, primary cough headache)
Secondary headache disorders (categories 5–12)	Posttraumatic headache; headache attributed to cranial or cervical vascular disorders; headache attributed to nonvascular intracranial disorder; headache associated with substances or their withdrawal; headache attributed to infection; headache attributed to disorder of homeostasis; headache or facial pain associated with disorder of cranium, neck, eyes, ears, nose sinuses, teeth, mouth, or other facial or cranial structures; headache attributed to psychiatric disorder
Cranial neuralgias and central causes of facial pain (category 13)	Trigeminal neuralgia; glossopharyngeal neuralgia; nervus intermedius neuralgia; superior laryngeal neuralgia; nasociliary neuralgia; supraorbital neuralgia; occipital neuralgia; neck-tongue syndrome; external compression headache; cold stimulus headache; constant pain caused by compression, irritation or distortion of cranial nerves or upper cervical roots by structural lesions; optic neuritis; ocular diabetic neuropathy; head and facial pain attributed to herpes zoster; Tolosa-Hunt syndrome; ophthalmoplegic migraine; anesthesia dolorosa; central poststroke pain; facial pain attributed to multiple sclerosis; persistent idiopathic facial pain; burning mouth syndrome
Other headache, cranial neuralgia, central or primary facial pain	Headache unspecified

^aFrom the Headache Classification Subcommittee, International Headache Society (2004), *Special issue on the international classification of headache disorders (2nd edn.)*, *Cephalalgia* **24**(supplement 1).

Table 5 Diagnostic criteria for migraine^a

Migraine without aura	A. At least five attacks fulfilling B–D B. Headache attacks lasting 4–72 h (untreated or unsuccessfully treated) C. Headache has at least two of the following characteristics: unilateral location, pulsating quality, moderate or severe pain intensity, aggravation by or causing avoidance of routine physical activity (e.g., walking or climbing stairs) D. During headache at least one of the following: nausea and/or vomiting, photophobia and phonophobia E. Not attributed to another disorder
Migraine with typical aura	A. At least two attacks fulfilling B–C B. Aura consisting of at least one of the following, but no motor weakness: fully reversible visual symptoms including positive features (e.g., flickering lights, spots, or lines) and/or negative features (i.e., loss of vision), fully reversible sensory symptoms including positive features (e.g., pins and needles) and/or negative features (i.e., numbness), fully reversible dysphasic speech disturbance C. At least two of the following: headache [1.21] fulfilling criteria B–D for migraine without aura; begins during the aura or follows aura within 60 min; headache [1.22] that does not fulfill criteria B–D for migraine without aura; begins during the aura or follows aura within 60 min; headache [1.23] does not occur during aura nor follows aura within 60 min D. Not attributed to another disorder

^aFrom the Headache Classification Subcommittee, International Headache Society (2004), *Special issue on the international classification of headache disorders (2nd edn.)*, *Cephalalgia* **24**(supplement 1).

following list) as the major branching point (**Figure 4**). SSNOOPs are:

- Systemic symptoms (fever or weight loss)
- Secondary risk factors: underlying disease (HIV or systemic cancer)
- Neurological symptoms or abnormal signs (confusion, impaired alertness or consciousness, neck stiffness, clumsiness, or weakness)
- Onset: sudden, abrupt, or split-second (first or worst)

- Older: new onset and progressive headache, especially in middle age (>50 years old)
- Previous headache history or headache progression: pattern change, first headache or different (change in attack frequency, severity, or new clinical features).

A variation of SSNOOP is SSNOOPP, which considers pain with local tenderness (e.g., jaw or temporal artery) as an additional red flag.

Table 6 Differential diagnosis of headache with transient neurological symptoms mimicking migraine with aura^a

Cerebrovascular disease	Dissection, ischemic stroke and transient ischemic attacks, hemorrhagic stroke, AVM, primary CNS vasculitis, cerebrovenous sinus/dural thrombosis, postpartum angiopathy
Drug-induced	Nitric oxide-releasing compounds (e.g., nitroglycerin, sildenafil), illicit drugs
Endocrine/metabolic disorders	Hypoglycemia
Inherited/genetic disorders	CADASIL, MELAS, OTC deficiency
Nonvascular intracranial disorders	Focal encephalitis and aseptic meningitis, primary or metastatic brain tumors, idiopathic intracranial hypertension, HANDL (PLP), systemic vasculitis (e.g., SLE and aPL syndrome), HIV
Traumatic disease	Posttraumatic headache, postwhiplash injury
Others	Ictal headaches, whiplash injury, cervicogenic headache, chiari malformation type I, glaucoma

^aaPL, antiphospholipid; AVM, arteriovenous malformation; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy; CNS, central nervous system; HANDL, headache, neurologic deficits, and cerebrospinal fluid lymphocytosis; HIV, human immunodeficiency virus; MELAS, mitochondrial encephalopathy with lactic acidosis and stroke-like episodes; OTC, ornithine transcarbamylase; PLP, pseudomigraine with lymphocytic pleocytosis; SLE, systemic lupus erythematosus.

Table 7 Overlap in symptoms of migraine pain and secondary headaches

<i>Symptom</i>	<i>Some examples of headache conditions</i>
Unilateral headache	Trauma, cluster headache, trigeminal autonomic cephalgia, migraine, cerebrovascular disease, idiopathic jabbing headache, sinusitis, eye/jaw disease, cervical spine disease, giant cell arteritis
Throbbing pain	Migraine, cerebrovascular disease, hypertensive headaches
Exacerbation with movement	Migraine, headache attributed to conditions that increase intracranial pressure, posttraumatic headache, Chiari malformation type I, benign cough headaches
Photophobia	Migraine, cluster headache, meningitis, posttraumatic headache, subarachnoid hemorrhage
Nausea, vomiting	Headache attributed to conditions that increase intracranial pressure, meningitis, intracranial hemorrhage, trauma

**Figure 4** Approach to the diagnosis of headache. Red flag represents any of the SSNOOPs. Adapted from the Neurology Ambassador Program with permission.

General medical and surgical histories, social and family histories, medications intake, and review of systems may provide clues to the diagnosis. For example, transient visual obscuration and intracranial noises may point to idiopathic intracranial hypertension. An antecedent motor vehicle accident within 6–12 months of the headache onset may indicate posttraumatic headache or whiplash headache. General and neurological examinations are an integral component of the assessment of patients with headaches. Papilledema, carotid bruits, neck limitation of motion, second trigeminal nerve branch or occipital triggers, tender temporal artery, and focal

or lateralizing signs can all provide important clues to the diagnosis.

Once the characteristic symptoms of a migraine headache are identified and red flags are not elicited, imaging studies are likely to reveal a significant intracranial abnormality in only approximately 0.2% of patients. A magnetic resonance imaging (MRI) study is the preferred test when imaging is indicated.

Management

General Principles

General management strategies for migraine follow the TEEM[®] principles, which are:

- Trust and establish a strong rapport with the patient.
- Educate the patient about the disease/condition, treatment plan, and compliance. A major reason for failed therapy in headache disorders is noncompliance and/or unmatched or unrealistic expectations (e.g., expecting a cure for migraine).
- Empower the patient.
- Measure.

It is crucial to establish an accurate diagnosis based on a detailed history and physical examination and

aided in special circumstances by neuroinvestigative techniques such as an MRI. It is also very important to systematically assess and follow up on the disease severity and disease-related disability by encouraging patients to maintain headache diaries in order to identify headache patterns, triggers, associated symptoms, response to intervention, and so on. The elicitation during the history of migraine comorbid conditions (Table 3) provides either opportunities to simplify treatment regimens (e.g., valproate for migraine and bipolar disease) or limitations on the use of certain medications (e.g., propranolol for migraine sufferers with asthma).

Pharmacotherapy of Migraine

Migraine pharmacotherapy can be divided into (1) the treatment of acute pain, (2) the treatment of associated symptoms, (3) traditional preventive agents, and (4) preemptive approaches when attacks have predictable triggers (e.g., menstruation). Preventive therapy for migraine is indicated for patients with (1) frequent or disabling attacks, (2) a prolonged aura, or (3) a poor response or intolerance to acute therapy.

Current acute therapy (Table 8) for migraine includes simple analgesics (e.g., acetaminophen) and compound analgesics (e.g., combined acetaminophen, aspirin, and caffeine; acetaminophen with codeine),

nonsteroidal anti-inflammatory drugs (NSAIDs, e.g., ibuprofen), migraine-specific therapies such as ergots (ergotamine and dihydroergotamine, DHE) and triptans (serotonin type-1B and 1D, 5-HT_{1B/D}, agonist), and adjuvant therapies such as metoclopramide for gastrointestinal disturbances. Over-the-counter non-specific therapies are well suited for low-severity migraine, but patients with more disabling attacks are better served by using migraine-specific agents. When at-home therapy fails, parenterally administered drugs such as DHE, which is often combined with other drugs such as prochlorperazine or metoclopramide, may be needed. The choice of acute or preventive therapy should be guided by evidence, when available.

Preventive therapy is ideally aimed at reducing attack frequency, severity, duration, and overall impact and at achieving synergy with abortive therapy to improve its effectiveness. Pharmacological prevention includes β -adrenergic blockers, anticonvulsant or antiepileptic drugs, antidepressants, calcium channel blockers, and NSAIDs. Evidence supports the use of group 1 drugs (Table 9) as the first-choice therapies in migraine prevention.

Nonpharmacological complementary and alternative (integrative) migraine therapy includes trigger-avoidance and physical and behavioral interventions.

Table 8 Acute migraine pharmacotherapy^a

<i>Drug class/mechanism</i>	<i>Drug/compound</i>	<i>Daily dose range (mg)</i>
Analgesics, simple	Acetaminophen	1000
Analgesics, compound	Acetaminophen + ASA + caffeine	600 + 400 + 200
	Acetaminophen + codeine	(250–500) + 30
	Isometheptane + dichloralphenazone + acetaminophen	(65–130) + (100–200) + (325–650)
Ergots	Nasal dihydroergotamine	2–4
	Ergotamine	1–6
Nonsteroidal anti-inflammatory drugs	Aspirin (ASA)	650–1000
	Diclofenac	50–100
	Flurbiprofen	100
	Ibuprofen	400–1200
	Ketoprofen	75–150
	Mefenamic acid	500
	Naproxen	750–825
	Rofecoxib	25–50
	Tolfenamic acid ^b	200
	Almotriptan	6.25–12.5
Triptans	Eletriptan	40–80
	Frovatriptan	2.5–5.0
	Naratriptan	1.0–2.5
	Rizatriptan	5–10
	Sumatriptan	25–100
	Zolmitriptan	2.5–5.0

Table 9 Migraine preventive therapy^a

	Group				
	1	2	3	4	5
Efficacy	+++	+ to ++	+++	+++	—
Evidence	Good	Limited	Consensus	Good	Good
Adverse events	Mild to severe	Mild to moderate	Mild to concerning	Concerning	
Examples	Amitriptyline, valproate, propranolol, topiramate, timolol	Verapamil, vitamin B ₂ , candesartan	Nortriptyline, phenelzine	Methysergide	Nifedipine

^a+ indicates efficacy established (+++ is highest); — indicates that there is no evidence for efficacy as migraine prophylaxis. Adapted from Buchanan, T. M. and Ramadan, N. M. (2006), Prophylactic pharmacotherapy for migraine headaches. *Seminars in Neurology* **26**(2), 188–198. Reprinted by permission.

A systematic review in 2000 led to the conclusion that relaxation training, biofeedback, and cognitive-behavioral therapy are proven treatments for migraine, but the evidence for physical treatments such as cervical manipulation and transcutaneous electrical nerve stimulation (TENS) is not as strong. Largely uncontrolled clinical trials support a role for acupuncture in migraine prevention, but two recent randomized trials failed to demonstrate that acupuncture is more effective than sham intervention.

Summary

Significant advances in the acute and prophylactic management of migraine headaches have emerged in recent years, providing relief for millions of migraine sufferers. Given that approximately 6% of men and 17% of women experience migraines, many untreated patients may benefit from proper diagnosis and treatment. Various treatment regimens for the prevention of migraines have proved effective, but long-term prognosis remains less well delineated.

Mineralocorticoid Receptor Gene
Genetic Variants in the Mineralocorticoid Receptor

Glossary

<i>Aldosterone</i>	The classic salt-retaining steroid hormone secreted from the zona glomerulosa of the adrenal cortex; its release is stimulated by the renin–angiotensin system and rising plasma potassium concentrations.
<i>Glucocorticoid hormones</i>	Hormones synthesized and secreted from the zona fasciculata by the adrenal gland in response to stress and also during the diurnal rhythm. The main endogenous glucocorticoids are corticosterone in rodents and cortisol in humans.
<i>Haplotypes</i>	Combinations of several single-nucleotide polymorphism (SNP) alleles on the same chromosome. Here an allele is one variant of a sequence on the DNA, for

Mineralocorticoid receptors (MRs)

Single-nucleotide polymorphism (SNP)

Splice variant

example, a certain SNP. Often several haplotypes can be found in a gene due to unique combinations of SNPs.

Intracellular receptors by which aldosterone acts in epithelial cells to promote sodium transport while mediating the glucocorticoid-like effects in nonepithelial cells. In the brain, MRs bind the glucocorticoid hormones (corticosterone and cortisol) and mediate the effect of these steroids on appraisal processes and the onset of the stress response.

A variation in DNA sequence that occurs with a frequency of at least 1%. SNPs can result in amino acid changes, if they are located in the coding region. If they are not in the coding region, they can influence gene regulation by effects on, for example, gene splicing or the promoter region or through the introduction of a stop codon.

mRNA splicing occurs following transcription leading to alternative different mature mRNA molecules, so-called splice variants. Splicing can be tissue specific and context dependent with effects on mRNA expression levels and potentially leading to alternative different proteins.

<i>Transactivational properties</i>	Effects different factors have on the control of gene expression.
<i>Zinc fingers</i>	A highly conserved protein domain consisting of about 30 amino acid residues enabling corticosteroid receptors to bind DNA. Steroid receptors have typically two of these domains, encoded by exon 3 and 4. Each domain contains four cysteine residues interacting with one zinc ion, which is crucial for the stability of this domain.

Mineralocorticoid receptors (MRs) have similar affinity for the naturally occurring glucocorticoids (corticosterone and cortisol) and the mineralocorticoid aldosterone. In the epithelia, such as in the kidney, colon, sweat glands and circumventricular organ of the brain, these MRs selectively bind aldosterone, in spite of the approximately 100- to 1000-fold higher concentrations of glucocorticoid hormone in humans. MR selectivity for aldosterone is maintained through the activity of 11 β -hydroxysteroid dehydrogenase (11 β HSD) type 2, which converts cortisol and corticosterone to inactive metabolites. Through this mechanism, aldosterone can regulate the electrolyte balance, blood volume, and blood pressure. In nonepithelial cells residing in the heart, blood vessels and brain, the MRs are nonselective due to virtual absence of 11 β HSD type 2. Accordingly, MRs are exposed to both aldosterone and excess glucocorticoid hormone.

In addition to the regulation of the electrolyte balance, aldosterone and MRs have been implicated in vascular inflammation and damage and in fibrosis in the heart. These actions seem to be relatively independent from the regulation of blood pressure and electrolyte balance. In the brain, the activation of MRs can induce drinking behavior, salt craving, and other effects aimed at reestablishing the electrolyte balance. However, MRs also play a crucial role in the maintenance of cellular stability, regulation of the hypothalamic-pituitary-adrenal (HPA) axis, behavioral adaptation, and cell homeostasis. The MRs involved in the latter functions are predominantly located in the hippocampus, where the receptors are activated by cortisol or corticosterone, due to the relative absence of 11 β HSD type 2. Finally, recent data indicate the expression of the MRs in adipose tissue, regulating adipocytes differentiation and thermogenesis.

On the binding of the ligand, aldosterone or cortisol/corticosterone, MRs translocate from the cytosol to the nucleus and bind as a homodimer to hormone responsive elements (HREs). Transcriptional activation occurs through direct interactions with

transcription factors and recruitment of co-regulator proteins. This recruitment is governed in part by the ligand and by the HRE. Co-regulator complexes are involved in chromatin remodeling and the recruitment of numerous other factors that are part of the transcriptional machinery.

Genetic variants of the MR gene (i.e. splice variants, deletions, insertions, or SNPs) probably have effects on these functions. These effects include not only an action on the electrolyte balance and cardiovascular control but also on vascular inflammation, behavior, HPA axis control, and homeostatic control mechanisms.

Mineralocorticoid Receptor Gene

The MR (NR3C2) is a member of the nuclear receptor family and resembles the glucocorticoid receptor (GR; NR3C1). In the DNA-binding domain, amino acid identity between MR and GR is approximately 94%, in the C-terminus 57%, and in the N-terminus less than 15%. Transcriptional regulation is mediated by the N-terminal part (exon 2, region AF-1a and AF-1b), plus a small part of the ligand-binding domain (C-terminus, AF-2). DNA binding involves residues in exons 3 and 4. Furthermore, exons 5–9 are involved in ligand binding, dimerization (with exons 3–4), heat shock protein (Hsp)90 binding, nuclear localization, and transcriptional regulation.

The MR gene is located on chromosome 4 (4q31.1) and has a size of approximately 350 kbp (this can be viewed on the Ensembl website). On a regular basis, new SNPs are being identified. The full protein contains 984 amino acids and has a size of approximately 107 kDa. Two (possibly three) exon 1s exist, which can join exon 2 (see [Figure 1](#)).

Genetic Variants in the Mineralocorticoid Receptor

Genetic Variability

Genetic variants can result from mutations causing deletions, insertions, or just changes of the nucleotide at a given position. Depending on the position in the genome, different effects on the phenotype can be observed. Genetic variants can affect protein structure or regulation through different mechanisms. Even single base pair substitutions can cause dramatic changes to the phenotype; however, the vast majority of such changes which reach appreciable frequencies in the population (referred to as single nucleotide polymorphisms, SNPs) are benign.

The number of different SNPs in the human genome is probably in the range of 3–4 million out of

Figure 1 Human MR variants. a, Reported single-nucleotide polymorphisms (SNPs) leading to amino acid changes; b, the three functional domains; c, splice variants and translational variants. The number of the exon is in bold: 1 α , 1 β , 1 γ , 2–9. The exons are flanked by upper and lower numbers, which indicate the codon (or amino acid), ending with 984 in exon 9. If the number is followed by a dot, the codon spans both exons. Translation starts in the beginning of exon 2 and ends in exon 9 (TGA), followed by an untranslated region (UTR). In a (upper part), the indicated SNPs leading to amino acid changes are shown (from the Ensembl website), with the addition of S810L (associated with hypertension in pregnancy). In a (lower part), specific SNPs are shown that are found to be associated with mineralocorticoid resistance. These have a very low frequency and are only found in specific kindreds. The effects of these SNPs can involve a frameshift (fs) or the introduction of a premature stop codon (st). In b, the three functional domains are shown: the transcriptional active domain, the DNA-binding domain, and the ligand-binding domain (which has several other functions). In c, although both exon 1 α and 1 β can join exon 2, this is not clear for exon 1 γ . In addition to most common annealing pattern (exons 2–9), exon skipping of exons 5 and 6 occurs, resulting in a frameshift with a new termination codon ending in exon 7 (position 2836). At the end of exon 3, 12 extra base pairs can be inserted due to alternative splicing (coding for Lys-Cys-Ser-Tyr), and joined with exon 4; this form is designated MR4+. KCSW, lysine-cysteine-serine-tryptophan.

a total of approximately 3 billion base pairs, counting only SNPs with a minor allele frequency of more than 1%. SNPs make up 90% of all human genetic variations, and two of every three SNPs substitute cytosine (C) with thymine (T), due to a high level of deamination of cytosine. These changes in nucleotide sequence give rise to alternative forms of a gene, named alleles. Combinations of several alleles on the same chromosomes are called haplotypes. However, not all possible combinations of the variants in a stretch of DNA are observed because of specific allele association or so-called linkage disequilibrium (LD). Often blocks of several SNPs are found, giving rise to several haplotypes in a gene.

SNPs are increasingly used to study the involvement of a certain gene and its protein product, in a complex phenotype, as is presented in psychiatric diseases. The association of an SNP in a given gene with a certain phenotype indicates the involvement of the gene. Alternatively, the carriers of a certain SNP/haplotype could represent a vulnerable (or protected) phenotype. Moreover, the determination of genetic variants could be used for more individual treatment of patients based on their specific needs, with respect to treatment efficacy and side effects.

However, several pitfalls are encountered when using variants in genetic research. Phenotyping is crucial because the effect of genetic variants are

often moderate, which also calls for the use of large numbers of subjects in association studies. The elucidation of the molecular mechanism of a functional variant will strengthen the *a priori* hypothesis and will also help identify which genetic variant in a given haplotype causes the observed phenotype. Finally, the replication of an association in an independent cohort of subjects will overcome the often observed false-positive associations.

Variants of the Human Mineralocorticoid Receptor Gene

Splicing variants Several alternative splicing variants exist at the 5' end of the gene: exon 1 α , exon 1 β , or exon 1 γ can join exon 2 (Figure 1c). The existence of exon 1 γ is still not completely clear. Upstream of exon 1 α and 1 β , many regulatory sites have been identified, and this region (P2 and P1) is considered the proximal promotor. The effect of the alternative use of exon 1s is still unresolved. However, during development a differential regulation and response to adrenalectomy of 1 α , 1 β , or 1 γ is observed in the rat hippocampal CA1, CA2, and CA3 pyramidal cell fields and the dentate gyrus (DG) neurons.

In the human MR, a 12-bp insert directly adjacent to the 3' end of exon 3, as a result of alternative splicing, has been found. The result is four extra amino acids (lysine-cysteine-serine-tryptophan; KCSW) in between the two zinc (Zn)-fingers involved in DNA binding. No clear effect of this splice variant, especially on DNA binding, was found. It is, however, expressed in most human tissues, with relative levels varying from 5 to 50%, compared to the most common MR.

Another human MR isoform is derived from skipping exons 5 and 6 with a resultant premature stop, giving rise to a protein of 75 kDa, retaining DNA-binding capacity and ligand-independent transcriptional activity. The high level of expression of this splice variant makes it a potential important modulator of MR effects.

Translational variants also exist as a result of the alternative use of different translational start sites. Two different forms of the MR, designated MR-A and MR-B have recently been described, with different transcriptional activities.

Cardiovascular control Research into the molecular mechanism of mineralocorticoid resistance or pseudohypoaldosteronism (PHA1), characterized by urinary salt wasting and hypotension, has revealed several inactivating mutations in the MR gene. Two forms of PHA1 exist: an autosomal dominant form

that is mild and a recessive form that is more severe due to defects in the epithelial sodium channel. In the autosomal dominant form, the target organ defect is confined to the kidney and clinical expression varies from asymptomatic to moderate. It may be severe at birth, with a failure to thrive, but symptoms often remit with age. The frequency of these mutations, including frameshifts, splice-site mutations, and premature stop codons, is quite low, which accords with the fact that PHA1 is a relatively rare disease. The usefulness of these mutations lies primarily in the understanding of MR protein activity with respect to DNA binding, translocation, and transactivational properties.

An activating mutation in the MR has been detected in patients with severe hypertension, which is exacerbated in pregnancy. The mutation, serine to leucine (S810L; Figure 1a), was found to alter the MR ligand specificity; progesterone and other steroids lacking the C-21-OH group became agonists.

Stress responsiveness Mutations of the MR may compromise the role of this receptor in the control of neuronal stability and stress responsiveness. Indeed Brown Norway (BN) rats are, compared to Fisher rats, insensitive to adrenalectomy because there is no weight loss and resistance to saline intake. In the BN-rat MR gene, a tyrosine to cysteine (Y73C) substitution was detected. This mutation revealed a greater transactivational activity of aldosterone and, interestingly, also of progesterone, suggesting that the MR is constitutively more active in the BN rat. It is of interest to note that BN rats have a long life span and seem to have a relatively stable HPA axis, compared to other rat strains.

In humans, some SNPs have a high enough frequency to be potentially important for stress-related disorders, such as anxiety and depression. We found the MR 180V (MRI180V, isoleucine to valine; allele frequency 11%) to be associated with measures of depression in an elderly cohort. In human 180V carriers (i.e., the heterozygote I180V and the homozygote V180V genotypes), cortisol levels and heart rate were enhanced in response to psychological challenge evoked in the Trier Social Stress Test (Trier Social Stress Test), whereas the SNP was not associated with changes in blood pressure in response to salt loading as part of the Weinberger's test. Moreover, *in vitro* the response of the MR 180V allele to cortisol was attenuated, which was not observed with aldosterone. The finding suggests that such a subtle SNP can have profound effects on stress responsiveness with potentially important consequences for stress-related pathology.

Basic Issues

Disadvantaged Minorities

Treatment Considerations

Glossary

Culture

Refers to the dominant set of symbolic codes (linguistic, moral, aesthetic) and material practices (dietary, behavioral) that characterize a group. Culture may

refer to an entire society's codes and practices, as when reference is made to the American or Japanese culture.

Deculturated

When people lose their culture or cannot use it because of changed circumstances.

Discrimination

A negating selection and differential comparison not based on merit.

Ethnicity

Refers to the particular reference group for individuals with a shared heritage, e.g., Puerto Rican, American Jewish. Some reference groups may be voluntary, such as those based on religion. Others may be involuntarily ascribed to the persons, such as those based on race. A part of a population, numerically less than 50%, differing from others in some characteristics and often subjected to different treatment.

Minority

Prejudice

An injurious and intolerant preconceived judgment.

Racism

Intentional or unintentional bias directed at individuals or groups based upon notions of the superiority or inferiority of skin color.

Stress

In minority communities, stress occurs when an individual or group's resources are overextended, even to the point of causing paralysis, apprehension, disintegration, and ineffectiveness from perceived and/or actual duress and assaults from the majority community.

Basic Issues

The basic issues in discussing minorities and stress include defining minority, differentiating the individual's stress from the stress of his or her minority group, and deciding which minority variables are best studied.

Who Is a Minority?

Everyone can claim multiple minority memberships. In fact, an individual may only or best be described in terms of such memberships. For instance, there are over 6000 languages in the world. Everyone's native language is a minority language. No one can claim majority status in terms of nationality, age, occupation, religion, avocation, or talent. Some minority memberships bring honor, others dishonor. Minority memberships may be forced or sought. They can be voluntary or involuntary. Many memberships are visible, often relating to appearance, including bodily features, uniforms, and insignia. Language usage can suggest a minority status. However, many minority memberships are invisible and can even be kept secret, such as migrant status, transnational allegiance, racial identity, and political and social affiliations.

Cultural and social forces determine the saliency of minority memberships. Humans create hierarchies, which in turn breed class distinctions, whereby minorities are made through a process of exclusion or inclusion. Rules of membership can be flexible or rigid, fluid or static. In a given community one might be in the most favored economic group but the least favored social group. Many minority memberships find favor or disfavor from legal regulations.

No matter which minority memberships one has, there are two conditions that must be negotiated for each minority membership. On the one hand, an accommodation for being acculturated and/or deculturated is made. On the other hand, some people or agency has to accept you as a member of the group. Such certification, written or unwritten, can be meticulous or arbitrary. The evaluation may not be accurate, complete, or satisfying to either the assessor or the assessed. Furthermore, certification of legitimacy may vary from the vantage point of various individuals, groups, and organizations.

Most individuals probably give little thought to most of their minority memberships. Therefore, they have not rank-ordered them. Yet, they are aware that the saliency and importance in their lives for any such membership is in a constant state of flux. The importance of a minority membership depends on the combination of specific, general, immediate, and far-flung circumstances at any moment and place.

These ever-shifting interpersonal interactions and intrapersonal considerations mean that in some sense an individual's minority status is situational. Furthermore, the situation depends both on what the individual perceives and on what other persons and groups perceive, even when there is agreement about exactly what minority membership is being scrutinized. Misperceptions between parties can range from being innocuous to being life-threatening. A common cause for misperceptions comes from different opinions about the speed, type, and quantity of acculturation. Also, views may differ significantly about how much a person or group is acculturated, should be acculturated, or can be acculturated.

Seldom is it possible to address these misperceptions among parties without the withering burden of stereotypical thinking by all participants. Thus, an obstacle in contemplating or negotiating a minority or majority issue is that all parties have confusion about what is unique to the individual versus what is a stereotype about a collective group.

The importance of and investment in any minority membership varies from person to person and even from time to time, whether or not one is a member of the in-group. Therefore, even with unequivocal certainty that one is a minority or one is dealing with a minority, the same stressors do not exert uniform force among the actors. Everyone attaches different valences to any minority status, even those that occupy his or her most intense concern. Furthermore, it is usually not possible to ascertain how much any participant identifies with, accepts, or knows about any minority membership that is under discussion.

Is Stress the Same for the Individual and the Group?

Stress results when resources are overextended and overwhelmed. There is the threat of dissolution with accompanying fears of abandonment and inability to escape. Stress is the reciprocal of support. Theoretically, perfect biological, sociological, and psychological support would equal no stress. Stress may be acute, chronic, or intermittent, with dimensions of intensity and duration.

Individuals in a group under stress will have varying perceptions and adjustments. These differences are mediated by both existing background factors

and factors peculiar to the stress. For instance, age, state of health, prior relevant experience, and faith are examples of attributes that help govern response to stress.

The number and general condition of a group under stress, as well as the quality of its leadership and its ability to be cohesive and cooperative, are important determinants of the group's outcome. Resourcefulness and a fierce will to survive increase the odds for a favorable outcome. The ability to take decisive, independent action is important.

In groups under stress, behavior of individuals speaks to the important aspect of group morale. Among such behaviors are the willingness to share, carefulness never to endanger the group, and the ability to perform multiple tasks.

Some individuals in any group thrive better than others. This seems true even when all the participants have similar backgrounds and quality of health. These individuals, for whatever reasons, may have more tolerance for uncertainty and ambiguity. Likewise, they may be more able to consider the consequences of the uncontrollable, the unpredictable, and the unexpected, with a more sanguine philosophy. In a mundane extreme environment such as a racial group living under oppression, such individuals may be more accepting of high risk and low reward, as the price for their own and their group's survival. Such persons are the group's everyday heroes, who demonstrate the greatest hope in the group that relief and amelioration are in the future.

Stressful events, due to their limited duration and more discrete circumstances, may be easier to study than stressful backgrounds. Groups and individuals in a railroad crash may be more easily understood and supported than individuals undergoing daily stress. In stressful events the individuals are more conscious of and willing to work for the common survival of the group. This shared specific stressful event will become another minority membership for each participant.

However, individual minority background experiences are filled with so much randomness, variability, and strategy that they are not easily delineated for study. There is a wide range of responses by individual members exposed to the same general trauma. Proximate factors such as personal loss and pain, differences in exactly what was witnessed, and the quantity of available and accessible resources required are never identical. This alone determines a plethora of heterogeneous responses by minority individuals under stress.

Which Minority Variables Are Best Studied?

The great bulk of minority studies are performed on populations considered disadvantaged. They verify in

detail that, in general, life is more terrible for these subjects. The data are abundant in this verification, whether addressing health disparities, inequalities in the law, unfair housing and employment, discrepancies in educational opportunity and achievement, harshness in the criminal justice system, insensitivity to the needs of children, etc. The studies focus on vulnerable populations and indicate negative patterns of service, response, and rates of problems. They document that under all manner of geographic, demographic, and political climates these minorities fare poorly.

There is an awareness of, but underpublished interest in, the strengths of individuals in these groups. The strengths the groups had to have in order to survive are less emphasized. Probably methodologies have not evolved that can capture the extensiveness of life events that permit and sustain the host of strengths that differentiate disadvantaged minority people.

A related issue is the huge thrust on aspects of resiliency in these populations, without much consideration of resistance. Studies of resilience imply post-traumatic phenomena. Resistance inquiries seek to understand the defenses against the offenses delivered to the disadvantaged populations, in which trauma continues to accumulate but is deflected, minimized, or diluted.

Disadvantaged Minorities

Social, cultural, economic, and political pressures determine what minority memberships are designated as disadvantaged. They may share features as the result of such designation, but each majority community would elect, in its own manner, which groups are targeted and what form of disenfranchisement and handicap is appropriate.

General Characteristics

A society may have written and unwritten rules that designate a group as disadvantaged. Such groups are disenfranchised in numerous ways. It is permitted and expected that the group will be abused and exploited. They occupy the margins of the society, often fractionated and segregated. The groups are likely to be the source of both amusement and wrath for the general population. While given substantially less in the community, it is demanded that they do more for less reward.

Petitions for succor by the disadvantaged prompt exasperation, perplexity, and astonishment. Social machinery is elaborated and sustained that is designed to control, dominate, and disrespect the unworthies. As such, the designated disenfranchised group struggles for its security, safety, and livelihood.

The disadvantaged are tyrannized and easily disregarded, discounted, and trivialized. Even so, they are feared as social or economic competitors. Regardless of their powerlessness, they are dismissed as unproductive noncontributors. They may be resented on grounds of their standards and values. They are given blame but little sympathy for an improper identity. Often they are accused of inviting their own catastrophe. In many cases, such as being female or having colored skin, there is no way the person can banish that identifier.

An individual member of a disadvantaged minority may live a lifetime with little or no direct, overt discrimination. Of course, many are victims of hatred, including physical assault, destruction of possessions, deliberate neglect, and even death.

More common are everyday minor, but cumulative, aggressions and insults. For instance, a White couple approaches a well-dressed Black male in a luxury hotel lobby and requests a taxi. They assume, incorrectly, that the man is an employee. The lifelong toll from these microaggressions, both physiologically and psychologically, remains unstudied.

An abundance of comparative data demonstrates the hardship and adversity suffered by disadvantaged minorities. For instance, between 1996 and 2002, the gap between American White and Black wealth grew from 10:1 to 14:1. In the United States, White family wealth now is 14 times the median net worth of Black families. Blacks make twice as many emergency room and outpatient visits as Whites. They make a third fewer visits to a doctor's office, however. In 2003, the percentage of Whites with advanced degrees was twice that of Blacks with advanced degrees. The same numbers hold in the comparison of White and Black college graduates.

There are clear burdens and risks imposed on groups designated as disadvantaged. In general, they are treated unfairly, and their efforts to improve their conditions generate a significant portion of the world's stress and violence.

The historical circumstances of each country determine which groups are disadvantaged and what efforts are made to promote intergroup peace and prosperity. In the United States, as elsewhere, there are numerous disadvantaged minorities. Due to demographic considerations, the most important issue for the United States in the twenty-first century may relate to disadvantaged minorities. It is expected that during this century Whites will become the minority population. The reduced proportion of Whites probably will be accompanied by significant alterations in the influence and hegemony of Whites. How Whites, especially White males, respond to this shift, may be the defining activity of the United States in this century.

Typological Classification

Any classification scheme is both arbitrary and limited. It follows that there can be no complete agreement, since every citizen can use his or her own system. Overall, in the United States, those generally considered by the general public to be disadvantaged minority groups meet a few broad criteria. First, there is evidence, usually with academic credibility, that the designated status does bring uncommon burdens to both the designated member and the general society. Second, the designated minority usually has a long and continuous history regarding getting legal relief from specified ills. Third, in the view of the public, sometimes including members of the minority itself, the designated group inspires fear, requires restraint, and often is deserving of mild to severe punitive actions.

There are those who are constitutionally handicapped. People are born into this category. These include women as well as selected racial/ethnic groups. The groups selected by the United States government include Blacks, Hispanics, Asians, and Native Americans.

The other large category, which most of the public considers disadvantaged, makes up a disparate miscellany. In this general group are migrants, the disabled, criminals, religious and cult community groups, especially those distant from core Christian organizations, and people with a variety of conditions in which there is some disagreement as to how much genetics is at fault. These conditions include obesity, homosexuality, alcohol and drug addiction, and sexual deviations.

All the groups in this classification scheme have been persecuted. For instance, Blacks were enslaved, Native Americans were objects for official genocide, and Hispanics lost large tracts of land to the United States. In general, in the United States, cross-racial interactions, particularly between White and colored races, has brought conflict and stress.

Special Obstacles

Designated minorities meet ongoing stress in an attempt to overcome obstacles in pursuing an occupation, finding adequate housing, and attracting political benefits. Always they remain sensitive as to whether they are welcome or merely tolerated. There is the ceaseless focus on how much, how fast, and in which ways the person and the group accommodate to or resist oppression.

All the separate disadvantaged minorities in the categorization have their own issues. For instance, in the racial/ethnic group there is enormous ambivalence about the cost of integration in such terms as increased intermarriage and loss of unity and leadership as segregated housing diminishes.

As another example, many migrants remain closely tied to their country of origin. The economy of entire countries would be seriously impaired without the input of dollars remitted by migrant workers in the United States. Some migrants in the United States exercise voting rights in other countries. Strong transnational loyalty has to be balanced against charges of diluted loyalty from host nationals.

In this age of wide and rapid communication, designated disenfranchised groups know, as studies show, that bad behavior by one of them has a disproportionate and negative impact on the memory and attitude of majority citizens. The problem of having little control over portrayal by the media becomes a vexing issue of some magnitude.

All the disadvantaged groups protest that the rules are constantly and covertly altered. The fundamental belief is that their space, time, energy, and mobility should be limited and serve majority purposes. This makes the quest for equality all the more elusive, since rules once learned and a system once understood become mystifying and obfuscating.

An advantaged population tends not to see any special, unmerited, or unjustified privilege in what it does. Similarly, it may not calculate any disadvantage from having privilege. Not counting the cost to themselves of disenfranchising whole groups brings serious consequences to the majority. However, if the police have permission to exercise tactics in the disadvantaged community that would not be allowed in the advantaged community, it means that the entire community has elements of a police state. Well over 25% of Americans are in a disadvantaged group. The United States operates under the stress of a huge disadvantage. Any body politic that functions at less than 100% potential is handicapped. The oppressing portion of a society has an obstacle to its own achievement when it does not count the cost of oppressive behavior in everything from total gross national product to intellectual, cultural, and technical achievement, as well as personal freedom.

Treatment Considerations

History teaches that minority groups do best when they themselves are unrelenting in seeking redress from wrongs inflicted upon them. The broad societal pressures are exerted on and felt by all members of a disadvantaged minority. Yet it is hard to imagine how any one-on-one process, even if achieved, could eliminate a minority group's stress. Accordingly, treatment possibilities must be conceived on a grand scale. Only a broad approach can be sketched.

In the foreseeable future, direct medical interventions seem less promising than possible sociological

and psychological approaches. The aim in these approaches is to provide increased hope and increased esteem to both the whole disadvantaged group and its individual members. In order to accomplish this objective, the groups themselves must somehow articulate and agree upon who is in their group and what the group cherishes. It must decide what to preserve and what to relinquish in accomplishing intergroup amity. The tactics required to reach these goals involve decreasing stress and increasing adaptation. Political and social action is obligatory.

Decreasing Stress

The disadvantaged minorities and their allies will need to continue and enlarge concerted, dedicated, social, and political actions to decrease stress. Diverse, multiple means must be instituted to teach the group, especially its youngsters, to anticipate the future. To do this, the group will have to mobilize structures at home, in community organizations, at schools, and at churches. All media channels, especially the Internet, TV, and radio, must be enlisted to help. The substantive debate about the details of the subject matter needs participation by persons who will inform themselves, seek input from the community, and be mindful of the history of the group.

Stress research would predict that supplying ways to help oneself and securing more support would be curative. Among topics, for instance, for colored groups would be propaganda analysis to learn to modulate messages that promote defeatism, futility, and loss of self-respect; lifestyle education to indicate the available steps that need to be and can be taken to increase the quality and quantity of life; and cross-racial interactions to emphasize aspects of group dynamics that aid or hinder interpersonal relations.

Perhaps special focus for many groups needs to be on networking and applying demographic remedies. For instance, in the United States, the racially/ethnically disadvantaged compared to the general population tend to be younger, more segregated, and more urban. A firm command of information of this sort will allow framing the future in terms of possible strengths and weaknesses.

Increasing Adaptation

Hopelessness and helplessness are the chief enemies to those under stress. The overall need is to supply support. Corollary to this need is to maximize adaptation. That is, one must cope.

For members of disadvantaged groups and the group as a whole, adaptation, historically, has required education as the critical step toward opportunity.

Acquisition of exploitable skills and unquestioned competency in these skills are more difficult to obtain by disadvantaged minorities. Therefore, much of their social action and networking has to be aimed at securing education.

Community members can facilitate adaptation for each other by countermeasures against noxious environmental stimuli: simple acts of encouragement, providing positive feedback, and giving credit for coping. Similarly, coping is facilitated by encouraging the members under stress, particularly youngsters, to explore options and to be cautious about foreclosing on any opportunity. Community members in a cohesive, cooperative community can augment coping by helping their community provide proper sites and environment for relaxation, another requirement for those in need of surcease. A community may underestimate its ability to contribute to coping. Yet by finding ways to make the community as stable as possible and by trying to reduce feelings of isolation the coping process is facilitated.

People cope better when they do not romanticize the past; when they have a present, clear, and certain mission; and when they appreciate the importance and urgency of that mission. Community members, by their positive attitudes and expectations, can contribute to the individual's enthusiasm for the direction of his or her future.

In coping, helplessness and hopelessness are to be avoided. Their presence may be manifested clinically, particularly by depression and anxiety. Furthermore, depression and anxiety may be comorbid with addiction, violence, obesity, diabetes, and cardiovascular disease. Medical surveillance to prevent illness and medical intervention to treat illness are important considerations in helping disadvantaged minorities to cope.

It is here that ongoing research holds promise to help disadvantaged populations. Advances in molecular biochemistry, endocrinology, genetics, and neurobiology can bring great relief to individuals and families of disadvantaged minorities. Being sure that

medical care is accessible will depend somewhat on the political and social activities of the group itself.

Glossary

Apoptosis

The active process of controlled cellular self-destruction, which is intrinsically programmed. It plays an important role in the development of multicellular organisms and in the regulation and maintenance of cell populations in tissues depending on physiological and pathological conditions. It can be initiated by the mitochondrion in response to energy deficiency, oxidative stress, and increased Ca^{2+} , among other stimuli.

Mitochondria

Intracellular organelles containing their own genetic material and the enzymatic machinery for major metabolic pathways, including the citric acid cycle, fatty acid oxidation, and oxidative phosphorylation, and for apoptosis.

Oxidative phosphorylation

The coupling of electron transport in the respiratory chain to ATP synthesis via the proton gradient and ATP synthase in the presence of oxygen, which occurs at the inner mitochondrial membrane.

Oxidative stress

The imbalance between reactive oxygen species production and antioxidant defenses, resulting in cellular damage.

Reactive oxygen species (ROS)

Oxygen-containing chemical species with unpaired electrons that are highly reactive and function in cell-signaling processes but also, at higher level, can damage cellular macromolecules and participate in apoptosis.

Background on Mitochondria

Mitochondria play a pivotal role in cell homeostasis, housing multiple metabolic pathways (including the tricarboxylic acid-, β -oxidation- and urea cycle) and the oxidative phosphorylation machinery that generates energy in the form of ATP. Research during the last decade has extended the prevailing view of mitochondrial function well beyond their critical role in supplying energy. Mitochondria synthesize heme and steroid hormones; are important for intracellular Ca^{2+} metabolism and signaling; generate the majority of cellular reactive oxygen species (ROS); and serve as the cell's gatekeeper for apoptosis. They contain multiple copies of circular mitochondrial DNA (mtDNA) and function under dual genetic control. Both nuclear and mtDNA encode genes that modulate mitochondrial protein synthesis and import, enzymatic activities, biogenesis, and apoptosis.

Most of the ATP necessary to supply energy to tissues and organs is generated by the mitochondrial oxidative phosphorylation system (OXPHOS). Under aerobic conditions, electrons derived from the oxidation of glucose or fatty acids are transferred through the respiratory chain complexes I–IV. At each of the enzymatic complexes I, III, and IV, protons are pumped out of the mitochondrial matrix into the intermembrane space, generating an electrochemical gradient used by the fifth enzymatic complex (ATP synthase) to drive ATP synthesis.

Mitochondria consume more than 90% of the cell's oxygen and are therefore the main site of ROS production. ROS, including superoxide, hydrogen peroxide, and hydroxyl radicals, are generated as a by-product of mitochondrial activity, primarily at complexes I, II, and III of the respiratory chain. Normally, 2–5% of O_2 used in the mitochondria is metabolized into superoxide. The superoxide radicals are converted to hydrogen peroxide by superoxide dismutase (SOD), which can further form the highly reactive hydroxyl radical. Mitochondrial (Mn-SOD and glutathione peroxidase) and cytosolic (Cu-SOD and catalase) antioxidant enzymes help to scavenge the ROS and limit their toxicity.

ROS play a significant role in the regulation of cell-signaling processes and in cytoprotection; thus their controlled generation is necessary for cell survival. On the other hand, when produced in excess of cellular antioxidant reserves, lipid peroxidation,

mtDNA damage, OXPHOS dysfunction, and damage to Fe–S-containing enzymes ensue. Oxidative stress to nuclear or mtDNA results in strand breaks and base modifications, followed by cellular dysfunction, mutagenesis, and carcinogenesis.

Mitochondria are involved in cell death by at least three general mechanisms: the release of proteins that trigger the activation of the caspase family of proteases, the disruption of oxidative phosphorylation and ATP production, and the modification of the cellular reduction–oxidation (redox) potential. Each of those mechanisms can result in programmed cell death (apoptosis) or cell necrosis. The initiation of apoptosis occurs via the opening of the permeability transition pore (mtPTP) located in the inner mitochondrial membrane. The mtPTP is composed of the adenine nucleotide translocator (ANT), voltage-dependent anion channel (VDAC), Bax, Bcl2, cyclophilin D, and benzodiazepine receptor. The opening of the mtPTP leads to swelling of the mitochondrial inner membrane and the rupture of the outer membrane, followed by the release of

cytochrome c, procaspases 2,3,4, and caspase-activated deoxyribonuclease (CAD) into the cytoplasm. Cytochrome c activates apoptotic protease activating factor (Apaf-1), which first activates procaspase 2 and 9, and subsequently caspases 3, 6, and 7, inducing apoptosis. Another caspase-activating protein released by mitochondria is the apoptosis-inducing factor (AIF). AIF and endonuclease G are transported to the nucleus and initiate chromatin condensation and degradation. Depending on the amount of cytochrome c and caspase inhibitors available, the cell undergoes either necrosis or apoptosis. The Bcl-2 family proteins exhibit pro- and/or anti-apoptotic properties (Figure 1).

Given their critical role in cell physiology, it is obvious that mitochondria are among the first responders to various stressful stimuli challenging cell homeostasis. They are responsible for meeting the enormous energy demands of the fight-or-flight response in vital tissues. Among other equally important effects, they control the fever response by the modulation of thermogenesis, balance the host immune

Figure 1 Mitochondrial functions. The figure illustrates (1) energy (ATP) production at the oxidative phosphorylation chain (OXPHOS) in the inner mitochondrial membrane, (2) reactive oxygen species (ROS) generation in the mitochondrial matrix and the enzymes Mn superoxide dismutase (MnSOD) and glutathione peroxidase (GPx), and (3) induction of apoptosis through the opening of the mitochondrial permeability transition pore (mtPTP). The OXPHOS complexes are complex I (NADH–ubiquinone oxidoreductase), complex II (succinate–ubiquinone oxidoreductase), complex III (ubiquinol–cytochrome c oxidoreductase), complex IV (cytochrome c oxidase), and complex V (ATP synthase). Ca^{2+} defuses through the outer membrane via the voltage-dependent anion channel (VDAC). The VDAC together with adenine nucleotide translocator (ANT), Bax, and cyclophilin D (CD) are components of the mtPTP. The release of cytochrome c (CytC) in the cytoplasm activates apoptotic protease activating factor (Apaf-1) and subsequently caspases that eventually lead to proteolysis and apoptosis.

response during infection by deciding on the fate of the affected cells, and adjust the oxidative stress response for cytoprotective and signaling purposes.

Mitochondria as Targets for Stress Hormones and Mediators

Several important mediators of the stress response, namely hormones (glucocorticoids, GCs, and catecholamines), immune mediators (cytokines), and heat shock proteins (Hsps), among other factors, exert multiple effects on mitochondrial biogenesis, metabolism, ROS generation, and apoptosis.

Glucocorticoids

GCs play a major role in survival during stress. Increased cortisol levels raise the resting energy expenditure and metabolic rate by as much as 200% during acute stress. Despite the significant hyperglycemia, the observed decrease in the respiratory quotient (the ratio of the carbon dioxide produced to oxygen consumed) suggests that a significant portion of that energy comes from the oxidation of lipids. GCs also stimulate protein degradation in muscle and lymphoid tissue to provide amino acids for gluconeogenesis in the liver.

In addition to the well-described molecular mechanism of GC action, via binding to glucocorticoid receptors (GRs) in the cytoplasm, and subsequent translocation of the GC-GR complexes to the nucleus for the trans-activation or -repression of nuclear gene targets, nongenomic mechanisms, such as the activation of phosphatidylinositol 3 (PI3) kinase and other cytosolic signaling pathways are increasingly recognized. Mitochondrial function can be affected directly or indirectly through both these mechanisms. Furthermore, GRs were recently described inside the mitochondria of several cell types, and mtDNA contains nucleotide sequences that are highly similar to the nuclear DNA GR binding consensus sequences. Thus, it is possible that GCs stimulate mtDNA transcription by direct interaction via the mitochondrial GR.

Indeed dexamethasone, a synthetic GC, stimulates the transcription of mtDNA-encoded genes (COX II and cyt-b) in hepatoma cell lines; a rise of mitochondrial transcripts (COX I, II, and III) was also found in colon epithelium of rats after dexamethasone injection. A recent study of rat skeletal muscle suggests an increase in mitochondrial biogenesis, mtDNA transcription (COX II and III), and cytochrome c activity after treatment with dexamethasone for 3 days. The mechanism underlying the observed transcriptional induction remains unclear because no increases in

mitochondrial transcription factor A (Tfam) or nuclear respiratory factor (NRF-1 and 2) have been observed in these studies.

Several studies suggest the modulation of mitochondrial metabolic activities by GCs in a biphasic mode. Low doses of or early exposure to GCs induce mitochondrial biogenesis and the enzymatic activity of selected subunits of the respiratory chain complexes, whereas higher doses or prolonged exposure cause increased ROS generation and respiratory chain dysfunction. Those effects depend on the target organ and developmental stage of the organism. Our recent transcriptional screening for mitochondrial targets of GC action in the human skeletal muscle revealed the induction of mitochondrial translation and energy metabolism-related genes after a shorter exposure to dexamethasone and the down-regulation of genes involved in lipid metabolism, induction of ROS, and apoptosis after prolonged exposure.

Clinical studies of the effects of chronic exposure to GCs have shown increased lactate production following aerobic exercise (suggesting anaerobic glycolysis due to mitochondrial dysfunction), decreased complex-I activity and oxidative damage-induced alterations in skeletal muscle mtDNA and nuclear DNA after long-term GC treatment. Moreover clinical symptoms resembling mitochondrial disorders, such as external ophthalmoplegia, have also been described under such conditions.

ROS generation follows exposure to GCs in different tissues. Hydrogen peroxide is described as a potent mediator of glucocorticoid effects in skeletal muscle cells, stimulating myogenesis and myotube formation at low doses while inducing apoptosis and cell death at higher concentrations or after prolonged treatment. GCs increase oxidative stress damage to neurons, in part by increasing glutamate and calcium and in part by decreasing antioxidant enzymes, specifically in the hippocampal neurons. Hydrogen peroxide is also synthesized in large amounts by neutrophils and macrophages during the oxidative burst, when it aids in destroying engulfed microorganisms. Moreover, various apoptotic stimuli, such as tumor necrosis factor (TNF)- α , have been shown to increase the levels of mitochondria-derived hydrogen peroxide. The increased production of hydrogen peroxide or superoxide after prolonged exposure to GCs in various tissues leads to mtDNA oxidative damage and apoptosis.

Interestingly, antioxidant compounds (i.e., N-acetyl-cysteine, vitamin C, and vitamin E) and enzymes (i.e., SOD and catalase) can prevent those adverse effects in skeletal muscle and vascular endothelium, both *in vitro* and *in vivo*. Those findings suggest a

primary pathogenetic role of ROS in GC-induced tissue damage.

GCs are important regulators of T-cell growth, differentiation, and apoptosis. Their profound anti-inflammatory and immunosuppressive activities place synthetic GCs among the most commonly prescribed drugs worldwide, especially for the treatment of hematological malignancies, such as leukemia and lymphoma.

The current evidence suggests that GC-induced cell death is linked to the *de novo* synthesis of one or several gene products. Genes described as being up- or downregulated during GC-induced apoptosis include c-myc139 and T-cell-death-associated gene (TDAG)8, Bcl-x_L, IκB, GILZ, and GITR. Interaction with other transcription factors, such as nuclear factor (NF)-κB, activator protein (AP)-1, nuclear factor of activated T cells (NF-AT), cAMP response element binding protein (CREB), and signal transducer and activator of transcription (STAT)5 is also critical. On the other hand, GC binding to its receptor rapidly induces ceramide generation via the activation of the phosphatidyl-inositol-specific phospholipase C (PIPLC) and acidic sphingomyelinase (aSMase) enzymes, which is necessary for caspase 9 activation.

A vast amount of data indicates that the disruption of mitochondrial integrity is a prerequisite for GC-induced apoptosis. This is tightly regulated by the balance between pro-(the BH-3 only: Bim, Bid, and Bad) and anti-apoptotic (Bcl-2 and Bcl-x_L) Bcl-2 family members, resulting in the activation of Bax and Bak, the opening of the mtPTP in the outer mitochondrial membrane, and the release of cytochrome c. The multimeric complex containing cytochrome c, caspase 9, and Apaf-1 (called the apoptosome) activates caspase 3, which finally leads to apoptosis.

Catecholamines

Catecholamines are the primary mediators of the fight-or-flight response. Norepinephrine is the major neurotransmitter in the peripheral sympathetic nervous system, whereas epinephrine is the primary hormone secreted by the adrenal medulla. The release of both is increased during stress. Their effect on target tissues is mediated by 6α- and 3β-adrenoceptor subtypes.

Epinephrine affects mitochondrial metabolism mainly by mobilizing body energy stores to augment the availability of substrates for oxidation. Epinephrine stimulates both lipolysis and glycogenolysis (most notably in the skeletal muscle) by interacting with the β₁- and β₂-adrenoceptors. It also acts through the G_s-protein-coupled β₂-adrenergic receptor to

stimulate adenylyl cyclase activity and cAMP production, leading to the activation of the protein kinase A (PKA). This signaling pathway is responsible for the modulation of numerous processes and notably gene transcription through the phosphorylation of CREB.

Another major mitochondria-targeted effect of catecholamines is the enhancement of thermogenesis, which occurs primarily in the brown adipose tissue, which is highly innervated by sympathetic nerve terminals. During this process, energy derived from the oxidation of fuel substrates is dissipated as heat rather than being stored as ATP (uncoupling). Uncoupling occurs via β₃-adrenergic stimulation and the downstream regulation of specific uncoupling proteins (UCPs). The inner mitochondrial membrane in brown adipose tissue contains UCP-1. Other known UCPs include UCP-2, which is widely expressed, and UCP-3, which seems to be expressed primarily in the skeletal muscles, heart, and brown adipose tissue, which are controlled by thyroid hormone and leptin. Several pharmaceutical companies have worked on the development of β₃-adrenoceptor agonists to stimulate UCP-1 in brown adipocytes and increase energy expenditure in obese patients. Unfortunately, these drugs often have adverse side effects on the cardiovascular system and poor bioavailability.

The peroxisome proliferator-activated receptor γ co-activator (PGC-1)α controls adaptive thermogenesis in adipose tissue and skeletal muscle by stimulating mitochondrial biogenesis and oxidative phosphorylation. Stress, fasting, and exercise activate the PGC-1α through different signaling pathways, including β-adrenergic (β₃/cAMP), Ca²⁺-dependent, NO and mitogen-activated protein kinase (MAPK) pathways. PGC-1α, in turn, activates the expression of nuclear respiratory factor (NRF)-1 and -2, estrogen-related receptor (ERR)-α, and PPAR-α, which regulate the mitochondrial biogenesis and fatty acid oxidation pathways. NRF-1 and NRF-2 regulate the expression of Tfam, a nuclear-encoded transcription factor that binds regulatory sites on mtDNA and is essential for the replication and transcription of the mitochondrial genome. Furthermore, NRF-1 and NRF-2 regulate the expression of nuclear genes encoding respiratory chain subunits and other proteins required for mitochondrial function.

Cytokines

The overproduction of inflammatory cytokines, with the subsequent induction of NO, platelet activating factor, and prostaglandins have been implicated in the changes leading to the multiorgan failure associated with, for example, sepsis. This pro-inflammatory

state is described as the systemic inflammatory response syndrome (SIRS).

Cytokines like TNF- α can induce apoptosis in several cell populations, whereas other cytokines such as interleukin (IL)-1 and IL-6 often inhibit apoptosis. The release of these pro-inflammatory cytokines is a major component of the stress response to infection, ischemia/reperfusion injury, and trauma. The intracellular signaling pathways involved in TNF- α - or Fas ligand (FasL)-induced apoptosis appear to be caspase 3-dependent.

Exciting new findings describing mitochondria localization of functional proteins required for the activation of interferon 1 expression in response to viral infections highlight the central role played by mitochondria in balancing the host immune response to viral infection and possibly to other pathogens.

Heat Shock Proteins

Hsps constitute a highly conserved and functionally interactive network of chaperones, some of which are constitutively expressed and others that are induced by various environmental, physical, and chemical stressors that challenge the intracellular milieu and cause damage to DNA and proteins. Chaperones are proteins that disaggregate, refold, and renature misfolded proteins, thus protecting the cell from the damage imposed by stressful stimuli. If the stressor is heat shock, the induced chaperones are called heat shock proteins.

The induction of Hsps following cellular damage can prevent apoptosis. Hsp27, 70, and 90 have been implicated in protection against apoptosis induced by multiple signals, such as heat shock, nutrient withdrawal, ROS, endoplasmic reticulum stress, proteasome inhibition, UV radiation, and chemotherapy-induced DNA damage. Hsps promote cell survival by preventing mitochondrial outer-membrane permeabilization and subsequent cytochrome c release, caspase activation, and apoptosome assembly. In addition, Hsp60 and Hsp70 interact with the outer mitochondrial membrane-specific translocase (TOM), contributing to the importing of nuclear-encoded proteins into the mitochondrial matrix. It may well be that the beneficial effects of fever initially described by Hippocrates actually relate to increased Hsp expression and their protective effects.

Mitochondrial Adaptation and Dysfunction during Acute and Chronic Stress

The acute response to stressful stimuli is characterized by the massive release of stress mediators. Their

coordinated interaction aims at (1) maintaining the effective circulation (and hence oxygenation) of the brain, cardiac muscle, and skeletal muscle; (2) increasing energy generation by the release of substrates (i.e., glucose, fatty acids, and amino acids) from body fuel storages (i.e., the liver, adipose tissue, and skeletal muscle); and (3) optimizing ATP availability to vital tissues at the expense of others (i.e., the gonads and gastrointestinal tract).

Tissue oxygen consumption and total energy expenditure are profoundly increased during the initial phase of the acute stress response. Rapid elevations in GC and catecholamine levels stimulate mitochondrial oxygen consumption and ATP formation to sustain the substantial hypermetabolic state. Mitochondria respond by modulating the expression and activity of certain OXPHOS subunits, or by increasing significantly their size and numbers (mitogenesis). Yet the exact mechanisms by which mitochondria fulfill this increased energy demand remain poorly understood.

Although the initial burst in mitochondrial function is necessary for survival, excessive mitochondrial activation during critical illness, such as trauma, surgery, or sepsis, can be detrimental to the cell ([Figure 2](#)). Stress-induced hyperglycemia, resulting from increased glucose mobilization and insulin resistance, is a common finding in these conditions, and its severity correlates strongly with increased mortality risk. Several lines of evidence support the concept that mitochondrial impairment, caused by glucose toxicity, is the underlying mechanism for the disturbance in oxygen use, called cytopathic hypoxia. Cellular glucose overload can exceed the capacity of the respiratory chain leading to (1) increased ROS generation and oxidative damage to the mitochondrial complexes I and IV, and the antioxidant enzyme MnSOD; (2) the impaired detoxification of superoxide and other free radicals; (3) the shunting of glucose into toxic pathways (i.e., polyol and hexosamine); and (4) increased apoptosis. Recent studies show that strict glycemic control with insulin therapy can prevent and correct mitochondrial ultrastructural and functional abnormalities in surgical intensive-care patients.

Prolonged physical and, interestingly, psychological stress can induce oxidative damage. In a recent study, psychological stress, both perceived stress and chronicity of stress, in mothers of children suffering from chronic illness was shown to be associated with increased markers of oxidative stress in their circulation (F₂-isoprostanes levels and isoprostanes/vitamin E ratio), in addition to telomere shortening. Telomeres are DNA sequences necessary for DNA replication, which shorten at cell division at a rate related to the levels of oxidative stress. Once telomeres are

Figure 2 Mitochondrial stress response under acute and chronic stress. Early exposure to glucocorticoids (GCs) or other stressful stimuli and their respective mediators induce mitochondrial biogenesis and the enzymatic activity of selected subunits of the respiratory chain complexes to meet the increased energy demands of the cell. Controlled production of reactive oxygen species (ROS), apoptosis, and thermogenesis serve as protective mechanisms against infection or other cell damage. Prolonged stress can exceed mitochondrial reserves, leading to respiratory chain dysfunction and decreased ATP production, increased ROS generation, and significant apoptosis and/or necrosis. mtDNA, mitochondrial DNA; NRF, nuclear respiratory factor; PGC, peroxisome proliferator-activated receptor γ co-activator; Tfam, mitochondrial transcription factor A.

shortened to a critical length, cells enter a stage of replicative senescence; hence, telomere length is a determinant of cell senescence and longevity. Although not examined in the study, it is expected that changes in the mtDNA, which is far more prone to oxidative damage, could also arise under those conditions. These findings have implications for the molecular mechanisms at the cellular level by which stress may promote the earlier onset of age-related diseases.

Psychological stress can lead to oxidative stress, but the opposite seems to hold true also. An intriguing recent study in an animal model showed a strong positive correlation between the expression levels of two antioxidant enzymes, glyoxalase and glutathione reductase 1, and anxiety levels. To determine whether those genes have a causal role in the genesis of anxiety, genetic manipulation was performed to induce or inhibit their activity. The local overexpression of these genes in the mouse brain resulted in increased anxiety-like behavior that was decreased with their inhibition. The authors propose oxidative stress as a new and unsuspected player in the complex control of anxious behavior, which, if exaggerated, in humans can be expressed as panic disorder, obsessive-compulsive disorder, posttraumatic stress disorder,

social and other specific phobias, and generalized anxiety disorder.

The metabolic syndrome (central/visceral obesity, insulin resistance, dyslipidemia, hypertension, pro-inflammatory, and prothrombotic syndrome) has been associated with hyperactivity of the hypothalamus-pituitary-adrenal axis. The pathogenesis remains unknown, but both genetic and environmental factors have an important share. It is proposed that underlying genetic polymorphisms or alterations in nuclear and, potentially more important, in mitochondrial DNA, in combination with exposure to environmental stresses such as excessive caloric intake, exhaust mitochondrial reserves and lead to the imbalance and failure of energy metabolism.

Support for this theory comes from numerous animal studies, across several species, which demonstrate the strong beneficial effects of calorie restriction on life expectancy. Reduced workload on the respiratory chain leads to improved energy output and decreased oxidative stress and subsequent damage. In this regard, a study that selected rats for their low versus high intrinsic capacity to run on a treadmill over 11 generations – hence, rats with low-versus high-power mitochondria – demonstrated that

cardiovascular risk factors, such as obesity, hyperglycemia, hyperlipidemia, hypertension, and insulin resistance, segregate with low aerobic capacity and reduced expression of genes required for mitochondrial biogenesis and oxidative phosphorylation.

Defects in mitochondrial fatty acid oxidation can lead to the intracellular accumulation of fatty acid metabolites that disrupt insulin signaling and possibly also secretion from the pancreatic β -cells, leading to insulin resistance and ultimately failure. Defects of mitochondrial oxidative phosphorylation and mitochondrial copy number are indeed observed in the skeletal muscle of elderly subjects and of healthy relatives of individuals with type 2 diabetes. Moreover, alterations in mtDNA, specific mutations in mitochondrial tRNA, or decreased expression of genes regulating mitochondrial function, such as PGC-1 α , are all associated with type 2 diabetes.

Transgenic animal models, in which antioxidant enzymes are overexpressed, such as manganese superoxide dismutase (MnSOD) or Cu,ZnSOD in *Drosophila*, exhibit a significantly extended life span. To the contrary, in knockouts for MnSOD, a 100% increased incidence of cancer was observed, whereas knockouts for mtDNA polymerase γ (POLG), the enzyme responsible for mtDNA proofreading, experience a significant acceleration in their aging process, with cardiomegaly, lipodystrophy, osteoporosis, anemia, and alopecia – but, interestingly, an absence of oxidative stress. The later study and others challenge the free-radical theory of aging and pose further questions in the fascinating field of mitochondrial pathology.

Seeking Mitochondrial Anti-stress Treatments

Therapeutic options for mitochondrial dysfunction are currently very limited. Strategies are being developed for mitochondria-targeted therapeutics, using their distinct biophysical and biochemical properties. The high negative potential of the mitochondrial matrix allows for selective targeting of positively charged compounds. Furthermore, the presence of specific transporter-dependent delivery for pro-drugs that can be subsequently activated by mitochondrial enzymes enable the design of highly specific agents.

The most effective of such attempts to date has been the development of mitochondria-targeted antioxidants. Mito-vitamin E and mito-coenzyme Q are coupled to a triphenylphosphonium cation, which accumulates several hundredfold in the mitochondrial matrix due to the large membrane potential, which is negative inside. First-line evidence from *in vitro* applications and initial animal studies on cardiac

ischemia-reperfusion injury have been very promising. Further support for mitochondria-targeted antioxidants comes from a transgenic mouse model, in which the overexpression of the antioxidant enzyme catalase targeted specifically to mitochondria (vs. to peroxisomes or the nucleus) significantly reduced oxidative damage in both nuclear and mitochondrial DNA, resulting in increased murine life span and delayed cardiac pathology and cataract development.

We can envision a rapid increase in the efforts to exploit the unique properties of mitochondria for the development of selective therapeutic agents aimed at increasing mitochondrial biogenesis and energy output while concomitantly minimizing mitochondrial Ca²⁺ overload, ROS production, and oxidative stress.

Stress and the Cycle of Violence

Genetic Factors in Aggression and Violence

MAOA as a Candidate Gene

The Role of Stress and Abusive Upbringing in Aggression and Violence

Conclusion

Glossary

<i>Allele</i>	One of two or more possible forms of a gene. An individual may possess two identical, or two different, alleles, except for those of the genes on the X chromosome in males because they possess only a single copy of this chromosome.
<i>Antisocial behavior (ASB)</i>	A pervasive pattern of disregard for and violation of the rights of others occurring since age 15 years old.
<i>Cycle of violence</i>	The observed relationship between violent parenting and violence in the parents' offspring.
<i>Major effect gene</i>	A gene whose influence can be detected without the need to control for environmental factors.
<i>Null mutation</i>	A mutation that completely eliminates the function of the gene.
<i>Promoter</i>	The section of DNA that precedes a gene and controls its activity.

Stress and the Cycle of Violence

A common observation in studies of ASB and aggression in humans is the cycle of violence, in which there is a tendency for individuals who were exposed to abusive parents and/or difficult childhoods to manifest antisocial personalities in adulthood. Not all individuals exposed to abusive childhoods, however, develop antisocial and violent tendencies. The challenge is, therefore, to establish the extent to which genetic predispositions and the extent to which stressful environments are responsible for eliciting the violent behavior. Recent research suggests that there is an interaction between the two that may underpin this repeating pattern.

Genetic Factors in Aggression and Violence

Results from more than 50 behavioral genetic studies indicate that, on average, approximately 41% of the variance of ASB is due to genetic factors, approximately 16% is due to shared environmental factors and approximately 43% is due to nonshared environmental factors. The same overall pattern appears to hold for violence. Epidemiological studies have also consistently shown that the risk of aggression is greater in males than in females, and this raises the possibility that genetic and environmental influences contribute differentially to the risk of aggressive behavior depending on gender. Twin studies indicate that common environmental factors, sex-specific genes,

and the interaction between the two play an important role in increasing liability toward aggressive behavior in males, even though females have a higher heritability and males a higher common environmental liability.

Evidence for a direct role of testosterone levels, which could be genetically determined, in promoting aggression in humans is not clear-cut. This leaves open the possible influence of other specific genetic factors that may contribute to increased aggression in males; recent interest has focused on the monoamine oxidase A gene, *MAOA*, in this regard.

***MAOA* as a Candidate Gene**

The main role for the monoamine oxidase (*MAOA*) enzyme is thought to be in degrading serotonin following its reuptake from the synaptic cleft, although it is also capable of degrading both norepinephrine and dopamine. It therefore plays a key role in the regulation of nerve transmission, and alterations in its activity produced by pharmacological intervention or through genetic variants are likely to have profound effects on behavior. Indeed, drugs inhibiting its activity have long been employed in the treatment of behavioral disorders, particularly depression.

A wide range of genetic variants of the *MAOA* gene exists in the general population. One of the most significant is a DNA motif localized in the promoter 1.2 kb upstream from the *MAOA* coding region, comprising a 30-bp repeat existing in 3, 3.5, 4, or 5 copies (Figure 1). It has been shown that the copy number has a significant effect on the level of the gene's expression. The two predominant forms observed in the population are those with three or four repeats of the motif, with the three-copy version having reduced transcriptional activity compared to the four-copy allele. The gene is located on the X chromosome, which means that females have two copies but males have only one. Any defect in the gene in males

is therefore exposed because they are unaffected by the status of a second copy.

A possible direct role for *MAOA* in predisposing violence, ASB, and conduct disorders was suggested by studies of males from a Dutch pedigree who exhibited a complex behavioral syndrome (including impulsive aggression). All affected individuals suffered from a mutation in the *MAOA* gene that resulted in zero activity of the enzyme. A role for *MAOA* deficiency in promoting aggression is further supported by studies on mutant mice that had deletions of portions of their monoamine oxidase gene, resulting in the lack of enzyme activity in the brain and liver. Behavioral studies on the adult male mice indicated heightened aggression in response to intruders and also increased inappropriate courtship behaviors. These have been the only reports to date of the phenotypic consequences of null mutations. The existence of high- and low-activity *MAOA* alleles in the human population, however, raises the intriguing possibility that lower levels of the enzyme may predispose male individuals to ASB and/or violent behavior.

There have been a variety of reports suggesting a role for variants at the *MAOA* locus in the context of violence and/or ASB, particularly in relation to subgroups of males with alcoholism and attention deficit and hyperactivity disorders. Generally, it appears that individuals with the low-activity allele are at risk, but there is no overall consensus concerning its possible status as a major effect gene. Nevertheless, a significant and intriguing interaction between stressful environments and low-activity variants of *MAOA* in promoting violence and ASB has recently emerged.

The Role of Stress and Abusive Upbringing in Aggression and Violence

Given the observed relationship between abusive environments and antisocial outcomes, the *MAOA*

Figure 1 Representation of the monoamine oxidase gene (*MAOA*). The promoter region (in diagonal lines) controls the levels of gene activity and contains a 30-bp repeat (often referred to as a variable-number tandem repeat, VNTR). Different copy numbers of the basic motif have different effects on transcription. Three- and four-copy motifs are the most common in the population, with the former conferring lower activity than the latter. Rare alleles with 2-, 3.5-, and 5-copy motifs are also observed. I indicates position of transcription initiation (RNA synthesis). Exons (coding regions) are in gray (not to scale).

gene became a candidate for a genetic predisposing factor that may interact with stress induced by adverse early rearing experiences to promote ASB. Caspi and associates, in 2002, were the first to study the interactions between environment and MAOA activity variants in the etiology of ASB in males by investigating the patterns of antisocial outcomes in a range of male children who had been maltreated. A broad range of measures for ASB was followed in the males from a longitudinal cohort of approximately 800 individuals who were age 26 at the time of data collection. The information available relevant to ASB included the commission of violent crimes, a personal disposition toward violence, and adolescent conduct disorder (assessed according to *Diagnostic and Statistical Manual*, 4th edn., criteria). Whichever measure of antisocial outcomes was examined, a significant association between maltreatment and ASB conditional on the individual's MAOA genotype was observed. Whereas maltreated males with low-activity alleles were significantly at risk of conviction for violent crime or of exhibiting other ASB, those with high-activity alleles were not. An increasing tendency to antisocial acts by those with more extreme childhood maltreatment was observed for males with the low-activity allele, but not for those protected by a high-activity allele.

Similar observations have since been reported in studies employing data from white male twins from the community-based longitudinal Virginia Twin Study for Adolescent Behavioural Development. Several other studies have been completed, and an analysis of all the information currently available is broadly supportive of an interaction between variants of this gene and stressful environments in predisposing ASB.

It is of interest that an analogous promoter variant system of this X chromosome gene has been discovered in rhesus macaque monkeys. A variable-repeat motif of 18 bp has been identified and shown to regulate the expression of MAOA. Of particular relevance to the putative role of functional MAOA variants in humans is that male macaques with the low-activity form were found to be more aggressive in competing for food.

The physiological relationship between the stress caused by abusive upbringing and the apparent protection provided by the high-activity allele for MAOA is not yet clear. Stress is known to elicit an increase in levels of transcription factors, such as c-Fos. These factors, in turn, may upregulate genes encoding components of neurotransmitter pathways, and it is possible that the apparent risk conferred by the low-activity allele of MAOA reflects a relative inability to respond to the effects of stress arising from maltreatment.

Conclusion

The lack of a functional copy of the MAOA gene in humans and mice results in ASB and aggression, and the less-functional fundamental variation of the gene appears to have related behavioral consequences. In particular, there is a complex interaction between the response to chronic stress and functional variants of the gene and the likelihood of individuals developing ASB or violent behavior. Longitudinal studies of the effects of childhood maltreatment and its interaction in males with high- or low-activity genetic variants of the MAOA gene suggest that the high-activity allele may confer protection in males because carriers are much less likely to develop ASB and aggressive behavior than are those with low-activity alleles.

Introduction

Psychological Disorder Following MVAs

What Predicts Psychopathology Following MVAs?

What Predicts Remission of Psychological Disorder?

Conclusion

Glossary

<i>Comorbidity</i>	The simultaneous presence of two disorders in the same individual.
<i>Longitudinal studies</i>	Studies that assess individuals at multiple points in time in a prospective manner.
<i>Prevalence</i>	Total number of cases of a particular disorder over a given period of time.
<i>Psycho-pathology</i>	Difficulty with psychological functioning (e.g., depression, anxiety, alcohol abuse).
<i>Spontaneous remission</i>	The alleviation of signs and symptoms of a particular disorder in the absence of formal treatment.

Introduction

The negative impact that motor vehicle accidents (MVAs) have on society is staggering. Total property damage, health-care expenditure, and hours lost from

employment have a cost to the U.S. economy of over 150 billion dollars each year. Moreover, the individual psychosocial consequences of MVAs can be very debilitating. Motor vehicle accident survivors often deal with complicated issues for the rest of their lifetime subsequent to an accident that may have lasted a total of 3 s. It is not uncommon for MVA survivors to face such complicated issues as bereavement, chronic pain, permanent disability, financial problems, loss of employment, depression, a variety of anxiety problems, and legal difficulties. Space limitations prevent us from covering all of these topics in detail. This article does not cover such interesting topics as the role that litigation plays in posttrauma recovery, the experimental investigation of posttrauma psychiatric symptoms, and the role of psychosocial treatments for MVA survivors. This article summarizes the literature on the chief behavioral problems that follow MVAs: specific phobia, posttraumatic stress disorder (PTSD), and major depression.

Psychological Disorder Following MVAs

Specific Phobia

A specific phobia is a behavioral disorder in which individuals manifest an excessive and unrealistic fear of a situation or object. Exposure to the feared situation will invariably provoke an anxiety response (e.g., situationally bound panic attack) from the phobic individual. Phobic individuals will deliberately avoid their feared situation or else endure the situation with great distress. Phobic fears can be seen in individuals with seemingly no traumatic history with the feared object or situation. Phobic fears can also develop via classical conditioning when aversive conditions are paired with the phobic object (which would not have been the target of phobic behavior at the time

of conditioning). MVAs can serve as a strong, single-trial conditioning event that leads to a phobic fear of driving-related situations in some individuals.

The experience of a MVA can be very frightening. Quite often, individuals will report that they experienced an extreme sense of life threat during the course of their accident. Thus, MVAs can serve as a single-trial conditioning event that will come to elicit anxiety responses (e.g., panic attacks) in future driving-related situations. For some individuals, the conditioned response is so severe that driving becomes exceedingly difficult. A small set of MVA survivors will discontinue driving following their MVAs, whereas others restrict their driving behavior relative to pre-MVA driving behavior.

The prevalence of a specific phobia of driving-related situations following MVAs is difficult to estimate. Some investigators have adopted a strict definition of driving phobia, wherein a complete elimination of driving or severe restriction of driving (i.e., only drives to work) defines phobic driving behavior. Others have adopted less restrictive criteria, defining driving phobias (sometimes termed driving reluctance) as a change in postaccident driving behavior characterized by increased anxiety related to some or all aspects of travel and a reduction in total number of miles traveled. Estimates of severe driving phobia (i.e., elimination or near-elimination of driving) are about 10–15% of MVA survivors. Estimates of less severe driving phobia or driving reluctance are between 38 and 77%.

Despite the general lack of diagnostic and prevalence data, one thing is clear: MVAs change the driving behavior of MVA survivors greatly. In countries where dependence on a private automobile is great, this can be a costly issue. Fortunately, exposure-based behavioral treatments can be very efficacious ways to treat driving phobia and reluctance to drive.

Posttraumatic Stress Disorder

PTSD is currently classified as an anxiety disorder by the American Psychiatric Association. It is a condition that follows exposure to an event that involves severe threat to one's life or physical integrity (e.g., wartime trauma, rape, MVAs). Following such life-threatening events, some individuals meeting the diagnostic criteria for PTSD will continue to reexperience their traumatic event in one of the following ways: psychological distress upon exposure to trauma-reminiscent cues, physiological arousal upon exposure to trauma-reminiscent cues, intrusive recollections of the trauma, trauma-related dreams that disrupt sleep, and flashbacks of the event. They also will evidence behavioral avoidance of trauma-related stimuli in much the same way that phobic individuals

will, as well as cognitive avoidance (trying not to think about the MVA). Depressive-type symptoms such as a restricted range of emotional experience and a loss of interest in pleasurable activities are also part of the symptomatic criteria. Finally, individuals meeting the diagnostic criteria for PTSD may have chronic hyperarousal, evincing such symptoms as sleep disturbance, exaggerated startle response, and difficulty concentrating.

Given the fear, sense of life threat, and extent of physical injury associated with severe MVAs, it is not surprising that a certain number of MVA survivors will develop PTSD. Prevalence estimates of PTSD among MVA survivors range from 1 to 46%. These discrepancies are due in large part to sample recruiting methods and diagnostic procedures. Self-referred clinical populations yield prevalence estimates of 40% or higher. However, more representative samples of consecutive accident admissions in hospital settings (i.e., emergency rooms) consistently yield prevalence rates near 20%. After reviewing the literature during the course of our work with MVA survivors, it is our impression that the most accurate prevalence estimate of PTSD following accidents is about 20%.

Studies that have examined this prevalence issue have varied in terms of time post-MVA that the patients were assessed. It is clear from longitudinal research that prevalence rates can vary greatly as a function of time postaccident. While many individuals will meet the criteria for PTSD in the first 1–4 months post-MVA, approximately 50% of those cases will spontaneously remit without formal intervention over the course of 6–12 months posttrauma. Thus, for MVA survivors who meet symptomatic criteria for PTSD shortly following trauma, many will experience a remission of symptoms without formal intervention. This spontaneous remission phenomenon is similar to that seen in PTSD populations subsequent to other traumas such as rape and wartime atrocity. What distinguishes those who remit vs. those who do not is covered in a later section of this article.

Major Depressive Disorder

Unipolar major depression is the most common mood disorder. Major depressive episodes are discrete periods of time (usually months to years) when individuals experience a variety of cognitive, affective, and physiological symptoms such as depressed mood, anhedonia, difficulty with concentration, feelings of worthlessness, sleep disturbance, appetite disturbance, psychomotor agitation/retardation, fatigue, and suicidal ideation or attempts.

Individuals often experience major depressive episodes in the months following their MVA. One

empirical question is whether the depression is a consequence of the MVA or whether the presenting individuals had problems with major depression prior to their MVA. Longitudinal studies suggest that a large number of individuals who experience major depressive episodes following MVAs are experiencing depression for the first time in their life. The incidence of depression during the time periods of these studies is greater than one would expect in non-MVA representative population samples during the same period of time. In addition, the onset of episodes is quite often close in time to the occurrence of the MVA. Considering these two findings, it is tempting to attribute causal status to MVAs for inducing major depressive episodes in some individuals. In addition, individuals who have had difficulties with major depression prior to their accident quite often experience another episode of depression following their MVA.

Thus, a large portion of the cases of major depression noted are a direct consequence of the MVA itself. Not surprisingly, major depression is a common comorbid condition with PTSD. The limited amount of research on the impact of comorbid depression with PTSD indicates poorer outcomes in major role functioning in individuals with comorbidity relative to individuals with one condition or the other.

What Predicts Psychopathology Following MVAs?

Phobic avoidance, PTSD, and major depression are more likely to occur post-MVA in individuals who are in more severe accidents. The severity of MVAs has generally been judged in two ways. First, subjective ratings of perceived life threat have been used as an index of severity of accident. Individuals who report a greater fear of death at the time of the MVA generally have more post-MVA psychopathology than those with a lower sense of life threat.

Second, the severity of MVAs has been assessed via more objective methods by quantifying the extent of physical injury incurred during the accident. Some studies have found this variable to have predictive power, in that the more severe the physical injuries, the more likely the individuals were to have behavioral problems. Other studies have failed to find such a relationship. Measurement differences may account for a large part of this variation. Some studies simply dichotomize the presence or absence of injury to predict psychological outcome in their data analyses, whereas other studies have quantified physical injury in a dimensional manner, assessing the range and severity of injuries through the use of instruments with good psychometric properties. Studies that use

these more reliable and valid physical assessment instruments are those that demonstrate the predictive utility of assessing physical injury. It is our impression that the degree of physical injury is a valid predictor of post-MVA psychopathology.

Consistent with research in other areas of trauma (i.e., rape trauma, wartime trauma), a history of previous trauma seems to be predictive of who will develop post-MVA psychopathology and who will not. Those with histories of previous trauma are more likely to have post-MVA psychopathology than those without previous trauma histories. The mechanisms that drive this cumulative trauma phenomenon are not known. Suffice it to say that previous trauma indicates a poor prognosis for survivors of serious MVAs.

Also consistent with the non-MVA trauma literature is the fact that previous psychopathology (preexisting depression, obsessive-compulsive disorder, etc.) indicates a poor prognosis for survivors of MVAs. Preexisting axis I disorders increase the likelihood of trauma-related diagnoses such as PTSD, specific phobia with traumatic onset, and major depression. This could be due to similar predispositions such as biological vulnerability, poor coping skills, and/or a lack of social support systems. It does appear that high levels of perceived social support are protective against the development of post-MVA psychopathology. These findings are entirely consistent with the literature that has assessed the relationship between social support and a variety of stress-related difficulties ranging from behavioral problems to immune functioning.

Gender has consistently been found to be predictive of psychopathology following MVAs. Women develop PTSD, major depression, and specific phobia at greater rates than men following MVAs. It may be that men are likely to cope with their problems by self-medicating with alcohol or drugs and thus present with different psychiatric diagnoses. The epidemiological literature as a whole would suggest that men are more likely to use alcohol and drugs as coping mechanisms.

What Predicts Remission of Psychological Disorder?

At a time when health-care resources are at a premium, a question of great interest to clinical researchers is, among MVA survivors with psychopathology shortly following an MVA, what variables will identify those individuals whose psychiatric symptoms will remit without intervention? Because treatment resources may not be available to all MVA victims (especially with accidents involving large numbers of individuals, i.e., bus accidents), the identification of

predictors of recovery is a very important applied question.

Not surprisingly, the degree of psychiatric symptomatology present shortly after the occurrence of MVA is predictive of remission of symptoms. Individuals with greater numbers of symptoms and more severe symptoms are less likely to show remission of diagnostic status than those who meet diagnostic criteria for disorder in the months post-MVA but have lower levels of symptomatology. The level of initial physical injury is also predictive of the remission of psychiatric symptoms. Those who are injured more severely at the time of MVA are less likely to show remission of psychiatric symptoms over time.

The rate of physical recovery, as assessed by self-report measures, is also predictive of psychiatric symptom remission. Those whose physical injuries recover at a slower rate also show a slower remission of psychiatric symptoms. The causal relationship between these variables is unknown. Some investigators have speculated that physical injury status, especially pain, exacerbates and maintains psychiatric symptoms, whereas others have argued that the presence of psychiatric symptoms makes people more sensitive to pain and thus more likely to inflate self-report scores of pain. This is a particularly vexing dilemma when trying to assess the rate of physical and emotional recovery in MVA survivors because many of their injuries are soft tissue injuries (e.g., cervical and lumbar spine strains), which do not lend themselves to quantifiable measurement other than by self-report methods.

Finally, the presence of behavioral avoidance shortly after trauma signifies a poor prognosis. Individuals who show a high degree of driving reluctance or avoidance shortly after their MVA are less likely to show a remission of psychiatric problems such as PTSD than those who force themselves to drive. It may be the case that self-administered exposure helps break the cycle of anxious responding in the presence of trauma-reminiscent cues that characterize PTSD.

Conclusion

Empirical investigation of the psychosocial consequences of MVAs is a growing field of research. Unfortunately, MVAs are a ubiquitous phenomenon in industrialized countries. The psychosocial consequences of MVAs are severe and many. Blanchard and Hickling is a valuable reference for clinicians who seek information about the psychosocial treatment of MVA survivors.

Glossary

<i>Antigen</i>	Molecule that initiates a response of the immune system; abbreviation of antibody generator.
<i>Immunoglobulin or antibody</i>	Protein that is produced by a specialized set of white blood cells (B lymphocytes) that has the capacity to specifically bind to antigens. This binding labels antigens for destruction by molecules and cells of the immune system.
<i>Infection</i>	Invasion and multiplication of microorganisms, which may lead to tissue damage and disease.
<i>Mucosa</i>	The mucus-coated lining of all body cavities and passages that form the interface with the outside world.
<i>Secretory immunity</i>	Protection against infection and noxious substances that is provided by the proteins present in the mucous secretions that coat the mucosa.

Introduction

Both human and animal studies have provided convincing evidence that psychosocial stress is associated with increased susceptibility to infectious disease. It has been estimated that 90 to 95% of all infections initiate at the mucosa; the mucus-secreting lining of all body cavities and passages that form the interface with the outside world. Examples are the soft oral tissues, the respiratory, gastrointestinal, and genitourinary tracts, and the eyes. Hence, investigating the

effects of stress on the immunological protection of the mucosa is an obvious starting point for research attempting to explain the link between stress and susceptibility to infectious diseases.

The mucosal surfaces are protected by the secretory immune system, which entails the secretions of a large number of local glands, including the salivary glands, the lacrimal glands, and the glands of the respiratory and gastrointestinal tracts. These glands secrete a wide variety of protective proteins (e.g., immunoglobulins, mucins, cystatins, lysozyme, lactoferrin) that constitute a first line of defense that prevents infection and disease by interfering with the entry and multiplication of microorganisms and noxious substances. This mucosal secretory immune system is under autonomic nervous system control, and it is well established that both acute and protracted psychological stress perturb autonomic nervous system activity. Thus, autonomic nervous system regulation of mucosal secretory immunity affords a plausible pathway by which psychological stress may increase disease susceptibility.

This article provides an overview of the research on stress and mucosal secretory immunity. Most research in this area has used saliva as a model system for studying mucosal secretory immunity. Moreover, of the many protective proteins that constitute secretory immunity, one protein, secretory immunoglobulin A (S-IgA), has attracted particular attention.

An Outline of Mucosal Secretory Immunity

The Secretory Immunoglobulins

Immunoglobulins (also called antibodies) are proteins that are secreted by specialized cells of the immune system, the B lymphocytes. Antibody production by the B lymphocytes is induced by foreign elements (called antigens), such as toxins, allergens, bacteria, and viruses. Upon interaction with an antigen, B lymphocytes rapidly divide and transform into immunoglobulin-producing plasma cells. A unique feature of immunoglobulins is that they have the capacity to bind (i.e., recognize) specific antigens, which helps with neutralizing or destroying this antigen. The most abundant immunoglobulin found in mucosal secretions is secretory immunoglobulin A (S-IgA).

S-IgA is produced locally by plasma cells that have migrated into the glandular tissues. Plasma cells in the salivary glands produce a polymeric form of IgA (as opposed to IgA found in plasma, which is

monomeric). This polymeric IgA (pIgA) is transported and secreted into saliva as S-IgA. The formation and secretion of S-IgA is a two-step process. First, the pIgA locks on to a receptor molecule, referred to as the polymeric-immunoglobulin receptor (pIgR), present on the basolateral surface of a glandular cell. The pIgR is translocated from the basolateral to the apical surface of the glandular cell, where it is cleaved off and secreted into saliva as S-IgA. Accordingly, both IgA secretion by the plasma cells and the availability of pIgR for translocation by the glandular cells are rate-determining steps in the secretion of S-IgA. The pIgA receptor itself can also be translocated and is subsequently secreted as secretory component (SC).

Human IgA occurs in two isotypic forms, IgA1 and IgA2. The most notable difference between the two is that IgA1 is more vulnerable to degradation by bacteria, which makes this IgA isotype less effective. This may explain why the less vulnerable IgA2 subclass is more abundant in mucosal secretions; whereas the IgA1 subclass makes up some 90% of the total IgA in serum, it comprises 60% of S-IgA in saliva and only 35% of S-IgA in the lower gastrointestinal tract.

Innate Secretory Immunity

S-IgA is only one of many protective proteins secreted in the fluids covering the mucosa. The secretion of

these other, innate immune factors (e.g., mucins, cystatins, lysozyme, lactoferrin) is also under strong neurohormonal control. Accordingly, these antimicrobial secretory proteins are also good candidates for psychoneuroimmunological investigation, although they currently received insufficient attention. [Table 1](#) lists several innate secretory factors that have been studied in this arena.

Neuroendocrine Regulation of Salivary S-IgA Secretion

As indicated, the synthesis and release of the secretory proteins by salivary glands and other mucosal secretory exocrine glands is under autonomic nervous system control, providing a sound neurobiological basis for anticipating an effect of stress on salivary secretory immunity. The preganglionic autonomic centers in the brain stem that regulate salivary gland activity receive direct inhibitory and excitatory inputs from brain areas that are part of recognized stress circuits and centers for homeostatic regulation. Studies with rats have shown that stimulation of both the sympathetic and parasympathetic autonomic nerves that innervate the salivary glands gives a rapid increase of S-IgA secretion into saliva, although the effect of sympathetic stimulation appears more robust than that of parasympathetic stimulation. Similar rapid

Table 1 Measures of innate secretory immunity that have been used in stress studies

<i>Secretory protein</i>	<i>Where found</i>	<i>Functions</i>
MUC5B (also denoted as MG1)	Saliva, nasal fluid, bronchial mucus, middle ear secretions, gall bladder epithelia	A mucin, i.e., a high-molecular-weight glycoprotein that consists largely (>75%) of carbohydrate. MUC5B is a major constituent of mucous gels covering the mucosa, where it protects against noxious substances and desiccation. Binds to a limited number of microorganisms. Host defense functions of MUC5B are enhanced by the formation of complexes with other secretory proteins.
MUC7 (also denoted as MG2)	Saliva, bronchial mucus	A mucin; binds and aggregates a large number of bacteria and fungi. Possibly also inactivate viruses.
Lactoferrin	Breast milk, nasal fluid, bronchial mucus, saliva, ocular fluid, and gastrointestinal secretions; also secreted by neutrophils	Inhibits microbial growth by binding iron, thereby depleting microorganisms from this essential substrate. Has anti-inflammatory effects and kills bacteria and fungi.
Lysozyme	Present in nearly all mucosal secretions including nasal fluid, bronchial mucus, saliva, ocular fluid, and gastrointestinal secretions; also secreted by neutrophils	Bacteriocidal by breaking down a cell wall component of gram-positive bacteria. Has also antimicrobial functions (growth-inhibiting, antiviral) through other mechanisms.
Cystatin S	Saliva, bronchial mucus	Cystatin S is a cystatin, i.e., protein that inhibits the activity of cysteine proteinases, thereby inhibiting enzymes that, among other things, are involved in virus replication and tissue invasion by bacteria.
α -Amylase	Saliva and pancreatic secretion. Low concentrations have also been demonstrated in other bodily fluids, including blood plasma, bronchial secretions, and tears	Starch-degrading enzyme. Influences the growth and tissue adhesion of streptococcal bacteria. Salivary α -amylase has been proposed as a measure of adrenergic activity, although this claim is still controversial.

increases in S-IgA secretion are observed in the gastrointestinal tract after stimulation of the local autonomic nerves. Autonomic stimulation of the salivary glands primarily affects the IgA translocation process and has little, if any, effect on IgA release by B lymphocytes.

It is still unclear whether the classic sympathetic transmitter norepinephrine is a major factor in the sympathetic stimulation on salivary S-IgA secretion. For example, the enhanced S-IgA output during moderate physical exercise, a strong sympathetic stimulus, is not attenuated by either alpha- or beta-adrenergic blockade in humans. An effect of sympathetic neuropeptides, which are coreleased with norepinephrine, has been demonstrated in animals. Other pharmacological studies in animals suggest that parasympathetic stimulation of S-IgA secretion may involve the classic parasympathetic transmitter acetylcholine and various neuropeptides.

Whereas autonomic stimulation may rapidly affect S-IgA levels, slower effects (>24 h) have been reported for glucocorticoids. The release of glucocorticoid hormones is considered central to the stress response. In rats, the synthetic glucocorticoid dexamethasone reduces both total salivary S-IgA and antigen-specific S-IgA levels. In contrast to salivary S-IgA levels, serum IgA levels are increased. Moreover, the expression of SC, the molecule that transports S-IgA into the secretions, is also increased. The effects of glucocorticoids on S-IgA secretion in humans remain to be studied, and since human and rodent S-IgA systems differ in several ways, findings for rodents should be generalized with caution.

In addition to direct stimulation of glandular S-IgA secretion, autonomic transmitters and glucocorticoids may indirectly affect the secretion of S-IgA by affecting immunological processes in the lymphoid tissues. Lymphoid organs are innervated by the autonomic nerves, and the residing immune cells carry functional receptors for the various autonomic transmitter substances. Indeed, autonomic nervous system activation has been shown to influence various aspects of local immune processing, including antigen presentation, antibody production, and cell migration. Thus, autonomic transmitters may also affect the S-IgA response by influencing the immunological priming of B lymphocytes in the lymphoid organs.

Stress and S-IgA

The Critical Distinction between Acute and Protracted Stress

The results of research on stress and S-IgA appear inconsistent at first glance. For example, some studies

report that S-IgA decreases during academic examination stress, whereas other studies report an increase. Research within psychoneuroimmunology has repeatedly demonstrated that acute and protracted stressors can generate opposing results on the same immunological parameters, and this also seems to apply to S-IgA. To illustrate this, Table 2 categorizes academic examination studies on the basis of whether saliva samples were collected close to (i.e., during, or minutes before or after) a single examination or sometime during the extended examination period. Sorting studies according to this single criterion reveals a remarkably consistent picture: all studies in which the samples were collected close to an actual examination were associated with increases in S-IgA, whereas nearly all of the remaining studies found decreases. Clearly, the acute stress of an imminent exam increases salivary S-IgA levels, whereas protracted academic stress is associated with a decrease. Note that these distinct S-IgA responses are independent of when the nonstress reference, or baseline, measurement is taken.

S-IgA and Chronic Stressors

There is a robust association between protracted (i.e., weeks to years) forms of stress, impaired immune

function, and health. Typical examples of such stressors are marital disruption, bereavement, caregiving for a severely ill spouse, and unemployment. Given the association between these types of stressors, immunity, and health, it is surprising that very few studies have examined S-IgA in this context. Nonetheless, a fairly consistent picture emerges from those that have. For example, lower salivary S-IgA levels have been observed in individuals distressed by living in parts of the United States stricken by environmental disasters (e.g., the Three Mile Island nuclear power plant, toxic waste sites in Delaware) than in individuals living in safer environments. Likewise, the academic stress studies cited previously (see [Table 2](#)) indicate that protracted academic pressures can lower salivary S-IgA levels.

A number of S-IgA studies have investigated chronic stress exposure by using self-report inventories. Such questionnaires typically request subjects to check a list of recent major life events (e.g., death of a spouse, divorce, loss of job) or minor daily hassles (e.g., minor conflicts and annoyances at home or work), or require subjects to give a general assessment of the stressfulness of their lives. The validity of this approach is established by prior research demonstrating that individuals scoring highly on such questionnaires exhibit increased susceptibility to a variety of infectious and inflammatory conditions, including respiratory infections and oral infectious diseases. The evidence provided by these questionnaire-based S-IgA studies also tends to support the hypothesis that higher levels of stress exposure and perceived stress are associated with lower levels of salivary S-IgA.

Despite consistent indications that chronic stressors lower S-IgA levels, methodological considerations temper a firm conclusion at this stage. For example, none of the studies controlled for potential sources of confounding, such as health behaviors (e.g., smoking, alcohol consumption), oral health, or medication usage. Further, many of the studies, including those with null results, tested small samples and/or used questionnaires with inferior psychometric properties. Thus, although largely supportive of the hypothesis that chronic stress lowers salivary S-IgA, there is a pressing need for a large-scale, well-controlled study to accurately assess the impact of perceived chronic stress on salivary S-IgA.

S-IgA and Acute Stress

Examination stress and other naturalistic stressors
The results of the academic examination studies summarized in [Table 2](#) indicate that the acute stress (of an imminent or ongoing examination) is associated with increased S-IgA levels. The fact that acute forms of

stress increase S-IgA levels is also confirmed by research using other stress paradigms. For example, S-IgA secretion is elevated in air traffic controllers following a stressful work shift. Also, S-IgA secretion is elevated in soccer coaches watching their team play. It should be noted that such acute increases are transient; S-IgA returns to baseline values typically within 1 h after acute stress exposure.

Laboratory stressors Further support for the hypothesis that acute stress increases salivary S-IgA is provided by studies that used conventional laboratory stressors such as computer games, mental arithmetic, and time-paced memory tests. These experiments, which are performed under highly controlled conditions, use stressors of short duration (5–30 min) that typically require mental effort and elicit robust sympathetic nervous system activation. The results consistently show increases in S-IgA concentrations ($\mu\text{g/ml}$) but tend to be somewhat less consistent regarding increases in S-IgA secretion rate ($\mu\text{g/min}$). This indicates that concomitant reductions in saliva flow rate contribute to the concentration increases during acute stress.

More recent studies have demonstrated that under some conditions, which include specific emotional states (e.g., disgust) and stimuli (e.g., pain, cold), S-IgA levels may transiently decrease. The mechanisms causing these rapid decreases have yet to be elucidated. Hedonic tone per se does not seem to determine the direction of the acute changes in S-IgA; both positive and negative emotional states (induced by imagery, listening to music tapes, or watching humorous sketches) have been associated with increases in S-IgA. Thus, apart from a few studies using painful stimuli or stimuli that induce disgust, virtually all types of acute states and virtually all experimental manipulations elicit an acute and transient rise in salivary S-IgA.

Stress and Oral Immunization

The research described thus far has concerned the effects of stress on total S-IgA levels. A few studies also investigated the effects of psychosocial stress on the daily variation in specific S-IgA, i.e., S-IgA that binds to a specific antigen. In these studies, participants were required to swallow a capsule containing rabbit albumin each morning for 8–12 weeks, and the daily variations in specific S-IgA (i.e., S-IgA directed against the rabbit protein) in saliva were measured in association with variations in daily mood and events. Antigen-specific S-IgA levels were lower on days with higher levels of negative mood and undesirable events and were elevated on days with more positive moods

and desirable events. Considering the pivotal role of the secretory immune defenses in protecting against infection, oral immunization provides an important and underutilized model for studying the effects of psychosocial factors on immune function.

The validity of the conventional method of measuring total S-IgA levels (as opposed to antigen-specific S-IgA levels described previously) has been a topic of heated debate. This debate, however, rests on the assumptions that S-IgA is a readout parameter for specific immune responses directed toward a particular antigen. If this were the case, only the levels of S-IgA molecules that are specifically directed against particular antigens would matter for host protection, rendering the measurement of total S-IgA levels less meaningful. However, total S-IgA for a large part consists of polyreactive antibodies (i.e., recognizing many different antigens). This broad specificity of S-IgA antibodies implies that total immunoglobulin levels, and not just antigen-specific levels, are important to mucosal protection. This idea is consistent with the evidence showing that total S-IgA levels predict the risk for respiratory and oral infections. Thus, the measurements of total and antigen-specific S-IgA levels seem to be immunologically meaningful ways of determining mucosal protection.

Effects on Secretory Component and S-IgA Subclasses

During acute stress in humans, the secretion of S-IgA appears to be regulated independently from the secretion of its transporter molecule, SC. For example, the passive stress induced by viewing a surgical video produced a rapid decrease in S-IgA secretion but an increase in the secretion of SC. During conventional active stress, a time-paced memory task, both S-IgA and SC secretion increased. It is as yet unclear whether these acute increases are due to increased endothelial transport or to a combination of increased IgA availability and transport into saliva. Both stress and physical exercise studies show that the rapid increases in S-IgA mainly reflect increases in the IgA1 subclass. The mechanism responsible for this subclass-specific effect is unknown.

Stress and Innate Secretory Immunity

Stress and Mucins

Two human studies have shown that acute stress enhances the secretion in saliva of the mucins MUC5B and MUC7. These findings are in line with the results of animal studies showing that increased gastrointestinal and respiratory mucin secretion

occurs in response to water immersion and restraint stress. These animal experiments also found effects on related biological processes, such as mucin synthesis and posttranslational processing (e.g., sulfatation, glycosylation). Pharmacological studies show that synthesis, posttranslational modification, and secretion of salivary mucins results, at least in part, from beta-adrenergic stimulation.

Stress-induced increases in salivary mucin may have consequences that benefit the host by enhancing mucosal barrier function, but also some that benefit microorganisms. For instance, the acute stress-induced increase in salivary MUC5B secretion enhances the adherence (*in vitro*) of *Helicobacter pylori*, a causative agent of duodenal ulcers and stomach cancer. Again, the effects of acute and protracted stressors may be quite different. For example, protracted stress decreases colonic mucin secretion in rats. This decrease in mucin secretion enhances mucosal permeability, thereby potentiating reactivation of experimental colitis induced by a chemical irritant.

Stress and α -Amylase

Studies in the early 1980s reported that salivary α -amylase concentration increases during relaxation and decreases with acute stress. However, later studies were unable to replicate these findings and instead found that acute stress increases salivary α -amylase concentration and secretion rate. These effects are again thought to result from stress-induced sympathetic activation, which would be consistent with the findings of studies showing that α -amylase secretion is increased by administration of adrenergic agonists, electrical stimulation of the local sympathetic nerves, and physical exercise. Moreover, increases in salivary α -amylase correlate with serum norepinephrine and cardiac left ventricular ejection time, a measure of cardiac sympathetic drive. Nonetheless, recent claims that salivary α -amylase is a valid noninvasive measure of adrenergic activity should be regarded with caution. First, α -amylase is also secreted in response to nonadrenergic sympathetic transmitters, i.e., various neuropeptides. Second, α -amylase secretion is also stimulated by parasympathetic stimulation, and parasympathetic stimulation augments the effects of sympathetic stimulation.

Stress and Other Mucosal Secretory Proteins

In humans, acute stressors that elicit sympathetic-parasympathetic coactivation increase the secretion of salivary cystatin S and lactoferrin, but no or only minimal effects are seen in response to a stress exposure that evokes sympathetic activation in

conjunction with a vagal withdrawal (a time-paced memory test). This finding is consistent with the notion that the two branches of the autonomic nervous system have a synergistic effect on secretory gland activity; that is, although sympathetic activation is the main stimulus for glandular protein secretion, the effects are strongly augmented by concurrent parasympathetic activity. As for more protracted stress, a decrease in salivary lysozyme secretion is observed during an examination period. The association between self-reported stress and salivary lysozyme levels appears inconsistent: one study found a negative correlation, whereas another did not find any association.

Stress and Microbial Colonization

A remaining, and critical, issue is whether the effects of stress on secretory immunity translate into functional changes, such as affecting processes that are involved in microbial colonization. Such functional effects might explain the alterations in mucosal microflora, seen in both humans and animals, under various forms of psychological strain, such as depression, space flight simulations, maternal separation, familial strains, animal fighting and relocation, and life events. Such effects may also explain the close association between stress and oral diseases with a bacterial etiology, such as periodontal disease and dental caries.

Aggregation is a process by which bacteria are clumped together through interactions with the host's secretory proteins so that these microorganisms cannot effectively adhere to the mucosal surfaces. Hence, a decreased bacterial aggregation indicates a decreased capacity for mucosal microbial clearance. Examination stress reduces the aggregation by saliva of the oral bacterium *Streptococcus gordonii*. A reduced streptococcal aggregation is also observed in rats administered physiological doses of the beta-adrenergic agonist isoproterenol for 1 week. This indicates that both brief and prolonged sympathetic activation can negatively affect the capacity of saliva to aggregate oral bacteria.

Microbial adhesion is a process by which microbes gain a stable foothold in the host; it constitutes a first and essential step in infection. Acute laboratory stress in humans enhances saliva-mediated adhesion of oral bacteria (viridans streptococci) and non-oral bacteria (*Helicobacter pylori*). Laboratory stress also affects the saliva-mediated adhesion of microorganisms to each other. Animal studies demonstrate that glucocorticoid administration is associated with an increased bacterial adherence to the intestinal mucosa and a

reduced luminal S-IgA. Similarly, in rats, 1 week of physiological doses of the beta-agonist isoproterenol increased the salivary adherence of *Streptococcus mutans*. Thus, stress, sympathetic activation, and elevated glucocorticoid levels promote the adhesion of microorganisms to mucosal surfaces.

Conclusion and Future Perspectives

Psychological stress has a variety of effects on mucosal salivary secretory immunity in humans, including altered secretion of adaptive and innate immune factors, reduced bacterial aggregation, increased bacterial adherence, and altered microbial coadherence. There is still little known about the effects of stress on secretory immunity in secretions other than saliva. The scant research in this area, mostly in rodents, confirms and extends the salivary findings in humans; there are effects on protein secretion, synthesis, and posttranslational modification, as well as on functional changes such as enhanced bacterial adherence and increased intestinal permeability.

In addition to an emphasis on salivary immunity, there has been a disproportional focus on S-IgA. The fact that individuals deficient in S-IgA, the most common form of immunodeficiency, are, for the most part, in good health suggests that other secretory factors may be important.

More attention also needs to be paid also to the effects of protracted stress exposure on secretory immunity. Knowledge about the effects of chronic stress on innate secretory immunity is practically absent, and the studies on chronic stress and S-IgA, although painting a fairly consistent picture, suffer from several methodological shortcomings. Further, the underlying mechanisms have yet to be fully elucidated. A promising model for studying the effects of chronic stress on adaptive secretory immunity is mucosal immunization.

Finally, researchers should extend their horizons to include the study of the functional implications of stress-induced changes in mucosal protein secretion. A number of microbiological methods are available to investigate the effects of immunosecretory changes on microbial colonization processes, which include viral invasion, bacterial adherence, bacterial growth, and bacterial aggregation. This approach, rarely considered in the realm of psychoneuroimmunology, may reveal the mechanisms by which immunosecretory changes affect the mucosal microflora and susceptibility to infection. Moreover, this methodology will help to strengthen the proposition that stress, via its effects on secretory immunity, has important health consequences.

ATP-binding cassette (ABC) transporters A large and multifunctional family of structurally related membrane proteins. ABC transporters use the energy of ATP

hydrolysis to pump substrates across cell membranes and are involved in the transmembrane transport of various substances.

The ability of cells to develop resistance to a broad range of structurally and functionally unrelated drugs after being exposed to (one of) these drugs. The mechanism is that the efflux transport by these proteins leads to lower intracellular concentrations, thereby protecting the cells and tissues from potential toxic compounds from the external milieu.

A group of MDR ABC transporters that are structurally related to but distinct from P-glycoproteins; mainly transports anionic derivatives of drugs when conjugated to glutathione/glucuronide. This family of MRP proteins comprises nine members in humans, designated MRP1–MRP6.

Multidrug resistance (MDR)

Multidrug resistance-related proteins (MRPs)

P glycoprotein (Pgp) The first discovered MDR transporter and most well-known ABC transporter; has been shown to transport a variety of structurally unrelated compounds across cellular membranes.

ATP-Binding Cassette Transporter Superfamily

The ABC transporters comprise a large and multi-functional family of structurally related membrane proteins that are located in the plasma membrane of the cells or in the membrane of various cellular organelles. ABC transporter proteins use the energy of ATP hydrolysis to translocate various molecules across these barriers, and some other ABC transporters use ATP to form specific membrane channels. The ABC transporters serve a variety of physiological roles, and also some inherited diseases appear to be linked to mutations in the genes encoding for the ABC transporters.

At present, approximately 50 ABC transporters are known. Many synonyms exist for these transporters due to their history of discovery. Recently, a consistent nomenclature has been introduced on the basis of the organization of domains and amino acid homology of these ABC transporters. In the new nomenclature, the ABC transporters are divided into seven distinct sub-families: ABCA, ABCB, ABCC, ABCD, ABCE, ABCF, and ABCG. [Table 1](#) presents the classification of these families and their members (including the synonyms), together with their expression, endogenous and exogenous substrates, functions, and relation to human disorders. It is clear that the ABC transporters govern the kinetics of chemical communication in the body, which makes the knowledge of their specific actions in homeostatic and feedback mechanisms extremely important for further insight into the body's functioning at the molecular level under normal and challenged (stress) conditions.

Multidrug Resistance Transporter Proteins

ABC transporters have been the subject of intense scrutiny as potential mediators of clinical drug resistance. The identification of the MDR1-encoded P-glycoprotein (Pgp) approximately 20 years ago, allowed us to recognize that reduced intracellular accumulation of anticancer agents can result in significant degrees of drug resistance. Over the years, Pgp has become the prototype of the MDR transporters. Among the ABC transporters, two other major groups can be identified as being involved in intrinsic and/or acquired MDR of cells: the multidrug

resistance-related protein (MRP) family and the breast cancer resistance protein (BCRP). Many drugs that have been developed for the treatment of human diseases are substrates for these multidrug transporters. Because of that, the degree of expression and the functionality of these transporters can directly affect the therapeutic effectiveness of such agents. Treatment failure due to MDR was first found in connection with cancer, but later in time it was also found in connection with other conditions such as some autoimmune disorders and infectious diseases ([Table 1](#)).

P-Glycoprotein

Pgp is the most well-known of the ABC transporters and was the first to be identified in humans, in which it plays a critical role in drug resistance in the treatment of cancers. Numerous investigations with many drugs have demonstrated that Pgp has an important role in determining the concentration–time profiles of Pgp substrates in the different parts of the body. In general, Pgp preferentially extrudes large hydrophobic, positively charged molecules. This transporter also is involved in the transport of certain cytokines. Pgp may even play a role in allograft rejection and in the inhibition of apoptosis. Another possible role of Pgp lies in the pathogenesis of Alzheimer's disease by the direct interaction of Pgp on amyloid- β 40 and amyloid- β 42 or by Pgp's influencing the accumulation of these proteins. Also, an interesting role for Pgp is indicated in the neuroendocrine functioning and regulation of the hypothalamic-pituitary-adrenocortical (HPA) axis because Pgp is involved in the efflux of certain natural and synthetic glucocorticoids from the brain.

Multidrug Resistance-Related Protein Family

The MRPs (or the ABCCs) have a broad tissue distribution and are able to extrude negatively charged anionic drugs and neutral drugs conjugated to glutathione, glucuronate, or sulfate. Some MRPs are able to transport neutral drugs if co-transported with glutathione. The total MRP family now includes MRP1–MRP9 (and ABCC7 and ABCC8). MRP1 was the first to be discovered and is actually a prototype glutathion conjugate pump that transports a variety of drugs conjugated to glutathione, sulfate, or glucuronate; anionic drugs and dyes; neutral-basic amphiphatic drugs; and even oxyanions. The most important substrate of MRP1 is the endogenous leukotriene LTC₄. MRP1 also contributes to the blood–cerebrospinal fluid (CSF) barrier at the level of the choroid epithelial cells. MRP2 and MRP3 have overlapping substrate specificities with MRP1 but different tissue distributions, and they appear also to exhibit drug resistance.

Table 1 ATP binding cassette transporter families and members^a

Family	Member (synonyms); most common name	Tissue expression	Physiological substrates; other substrates; inhibitors/modulators	Function	Genetic mutations related to human disease
ABCA	ABCA1 (ABC1, TGD, HDLDT1, CERP)	Ubiquitous (plasma membrane)	Phospholipids, cholesterol	Removal of phospholipids and cholesterol on to high-density lipoprotein particles	Tangier disease, atherosclerosis
	ABCA2 (ABC2)	Brain, kidney, lung, heart, lysosomal membrane	<i>Estramustine?</i>	Steroid transport?	
	ABCA3 (ABC3, ABCC)	Lung			
	ABCA4 (ABCR, ABC10, STGD)	Retina (rod photoreceptors)	<i>N-retinylidene-phosphatidyl-ethanolamine, retinaldehyde</i>		Stargardt disease, retinitis pigmentosa, macular dystrophy, cone-rod dystrophy
	ABCA5	Muscle, heart, testes			
	ABCA6	Liver			
	ABCA7	Spleen, thymus			
	ABCA8 (ABCR)	Ovary			
	ABCA9	Heart			
	ABCA10	Muscle, heart			
	ABCA11	Stomach			
	ABCA12	Low in all tissues			
ABCB	ABCB1 (MDR1, PGP, PGY1, GP170) P-Glycoprotein	Epithelial cells of kidney, liver, choroid plexus, intestine; endothelial cells of brain capillaries	IL-2, IL-4, IFN- γ , amyloid β -40, amyloid β -42, glucosylceramide, platelet-activating factor <i>Actinomycine D, aldosterone, amprenavir, bisantrene, calcein-M, citalopram, colchicine, corticosterone, cortisol, cyclosporin A, dexamethasone, digoxin, domperidone, doxorubicin, daunorubicin, enaminonen, erythromycine, etoposide, FK506, indinavir, loperamide, lovastatin, morphine, nelfinavir, ondansetron, paclitaxel (taxol), phenytoin, prednisolone, quinidine, rifampin, ritonavir, saquinavir, sparfloxacin, teniposide, terfenadine, (99m)-Tc-tetrofosfine, valspodar (PSC833), verapamil, vinblastine, vincristine</i> <i>Inhibitors:</i> Agosterol A, amiodarone, amitriptylin, amprenavir, biricodar (VX-710), chlorpromazin, cyclosporin A, diltiazem, dipyridamol, fluphenazin, GF120918, gramicidine D, LY335979, mefipriston, midazolam, nelfinavir, pimozin, pluronic L61, progesterone, promethazin, propafenone, propranolol, quinidine, reserpine, ritonavir, saquinavir, spironolactone, staurosporin, tamoxifen, trifluoperazin, triflupromazin, V-104, valinomycine, valspodar (PSC 833), verapamil	Multidrug resistance	

	ABCB2 (TAP1, PSF1, RING4, ABC17)	Ubiquitous (ER)	Peptides	Peptide transport (into the ER)	Juvenile-onset psoriasis; immune deficiency
	ABCB3 (TAP2, PSF2, RING11, ABC18)	Ubiquitous (ER)	Peptides	Peptide transport (into the ER)	Immune deficiency
	ABCB4 (PGP3, MDR3(2), PFIC-3)	Liver (hepatocytes)	Long-chain phosphatidyl-choline	Phosphatidylcholine transport	Progressive familial intrahepatic cholestasis-3, intrahepatic cholestasis of pregnancy
	ABCB5 (MTABC3)	Ubiquitous			
	ABCB6 (ABC14, UMAT, MTCA3)	Ubiquitous in mitochondria	Iron?	Iron transport	
	ABCB7 (ABC7, ATMIP, ASAT)	Ubiquitous in mitochondria	Iron?	Fe/S cluster transport	Sideroblastic anemia with ataxia
	ABCB8 (MABC1)	Mitochondria	Intermediates in heme/biosynthesis?		
	ABCB9	Lysosomes			
	ABCB10 (MTABC2)	Mitochondria			
	ABCB11 (sPGP, BSEP, PGY4)	Liver (hepatocytes)	Bile salts (e.g., taurocholate) <i>Paclitaxel (taxol)</i>	Bile salt transport	Progressive familial intrahepatic cholestasis-2
ABCC	ABCC1 (MRP1, MRP) Multidrug resistance related protein	Ubiquitous in normal tissues (mainly lung and choroid plexus epithelial cells) and brain capillary endothelial cells	17- β -glucuronyl estradiol, S-glutathionyl prostaglandin A2, glutathione disulfide, 4-hydroxynonenol-GS, leukotriene C4 (LTC4)-GS, leukotriene D4 (LTD4)-GS, leukotriene E4 (LTE4)-GS, NNAL-O-glucuronide lipid peroxidation products, nitroquinoline 1-oxide-GS <i>Aflatoxin B1-epoxide-GS, arsenite, arsenate (sodium), BCECF, calcein, chlorambucil-GS, colchicine, CPT-14, daunorubicin, DHEAS, 2,4-dinitrophenyl-GS, doxorubicin, epirubicin, ethacronic acid-GS, etoposide, fluorescein, flutamide, hydroxyflutamide, glucuronosyl etoposide, herbicides, heavy metals, indomethacin (-GS), melphalan-GS, methotrexate, rhodamine, ritonavir, sequinavir, ⁹⁹Tc-Sestambi, SN-38, SN-38-GS, SNARF, tobacco nitrosamines, ⁹⁹Tc-tetrofosmin, vinblastine, vincristine</i> <i>Inhibitors:</i> Agosterol A, benzbromarone, budesonide, biricodar (VX-710), cyclosporin A, indomethacin, probenecid, genistein, quercetin, sulfinylpyrazone, verapamil	Drug resistance, ubiquitous GS-X pump, immune response involving cysteneyl leukotrienes	
	ABCC2 (MRP2, cMOAT)	Liver, intestine, kidney, brain endothelial cells (plasma membrane)	Bilirubin-glucuronides, GSSH, GSH, including cotransport, estradiol-17- β -o-glucuronide, acidic bile salts <i>Anionic drug conjugates, cisplatin, doxorubicin, epirubicin, etoposide, indinavir, phenytoin, ritonavir, saquinavir, sulfinylpyrazome, vinblastine</i> <i>Inhibitors/modulators:</i> Leukotriene C4, probenecid	Organic anion efflux, hepatobiliary extrusion of amphipathic ions	Dubin–Johnson syndrome

Continued

Table 1 Continued

<i>Family</i>	<i>Member (synonyms); most common name</i>	<i>Tissue expression</i>	<i>Physiological substrates; other substrates;^b inhibitors/modulators</i>	<i>Function</i>	<i>Genetic mutations related to human disease</i>
	ABCC3 (MRP3, cMOAT-2)	Liver, bile ducts, gut, adrenal cortex of kidney, intestine, placenta	Bile salts, leukotriene C4 <i>Anionic drug conjugates, acetaminophen glucuronide methotrexate, etoposide, teniposide</i> <i>Inhibitors/modulators:</i> Probenecid	Drug resistance	
	ABCC4 (MRP4, MOAT-B)	Many tissues (plasma membrane)	Cyclic nucleotides, conjugated steroids and bile acids, DHEAS nucleotide analogs, 9-(2-phosphophenyl methoxyethyl)-adenine, prostaglandins, taurothiocholate 3-sulfate, thiopurine monophosphates <i>Nucleotide analogs, organic anions, nucleosides, monophosphates, zidovudine, other antiretroviral agents</i> <i>Inhibitors/modulators:</i> Probenecid	Nucleoside transport	
	ABCC5 (MRP5, MOAT-C)	Ubiquitous	Cyclic nucleotides, nucleotide analogs, 9-(2-phosphono- methoxyethyl) adenine, thiopurine monophosphates <i>Nucleotide analogs, organic anions nucleoside monophosphates, mitoxantrone, topotecan, doxorubicin</i> <i>Inhibitors/modulators:</i> Probenecid fumitremorgin C, GF120918	Nucleoside transport	
	ABCC6 (MRP6)	Kidney, liver (plasma membrane)	<i>BQ-123? (acidic peptide)</i>	Elastic tissue homeostasis	Pseudo-xanthoma elasticum
	ABCC7 (CFTR)	Exocrine tissues		Cystic fibrosis transmembrane conductance regulator (cAMP-dependent chloride channel)	Cystic fibrosis, CBAVD, pancreatitis, bronchiectasis
	ABCC8 (SUR1)	Pancreas		K(ATP) channel regulation	Familial persistent hyperinsulinemia hypoglycemia of infancy
	ABCC9 (SUR2)	Heart, muscle		Sulfonurea receptor	Dilated cardiomyopathy
	ABCC10 (MRP7)	Ubiquitous (low)			
	ABCC11 (MRP8)	Testis and breast, lower in all other tissues			
	ABCC12 (MRP9)	Brain and testis, lower in all other tissues			

ABCD	ABCD1 (ALD, ALDP)	Many tissues (peroxisomes)	VLCFA	VLCFA transport regulation	
	ABCD2 (ALD1, ALDR)	Many tissues (peroxisomes)	VLCFA	Adrenoleukodystrophy	
	ABCD3 (PMP70, PXMP1)	Many tissues (peroxisomes)	VLCFA		
	ABCD4 (PMP69, P70R)	Many tissues (peroxisomes)	VLCFA		
ABCE	ABCE1 (OABP)	Ovary, testes, spleen		Oligoadenylate-binding protein	
ABCF	ABCF1	Ubiquitous			
	ABCF2 (ABC50)	Ubiquitous			
	ABCF3	Ubiquitous			
ABCG	ABCG1 (ABC8, human white)	Ubiquitous		Cholesterol transport	
	ABCG2 (ABCP, MXR, BCRP)	Mainly in liver, placenta, small intestine; also in heart, lung, skeletal muscle, kidney, spleen, thymus, brain capillaries	Heme, porphyrins, flavanoids, pheophorbide, sulfated estrogens	Drug resistance, stem-cell differentiation, survival of stem cells (under hypoxic conditions).	HIV treatment?
	Breast cancer resistance protein		<i>Anthracyclines, bisantrene, diflomotecan, etoposide, flavopiridol, imatinib mesylate (STI-571, Gleevec), imatib, irinotecan, SN-38, methotrexate, mitoxantrone, lamivudine, rhodamine 123, teniposide, topotecan, zidovudine, Inhibitors/modulators</i> CI1033, futremorgirin C, GF120918, hammerhead ribozyme, HIV protease inhibitors, imatinib (STI-571, Gleevec) pantoprazole, prazosin, reserpine, ZD1839 (Iressa)		
	ABCG4 (white2)	Liver			
	ABCG5 (steroline 1)	Liver, intestine		Sterol transport, biliary cholesterol secretion/absorption	Sitosterolemia, sterol accumulation, atherosclerosis
	ABCG8 (steroline 2)	Liver, intestine		Sterol transport, biliary cholesterol secretion/absorption	Sitosterolemia, sterol accumulation, atherosclerosis

^aBCECF, 2',7'-bis(carboxyethyl)-5(6)-carboxyfluorescein; CBAVD, congenital bilateral absence of the vas deferens; CFTR, cystic fibrosis transmembrane conductance regulator; DHEAS, dehydroepiandrosterone; ER, endoplasmic reticulum; GSH, glutathione; GSSH, glutathione persulfide; GS-X, GSH conjugate; HIV, human immunodeficiency virus; IFN, interferon; IL, interleukin; PMEA, 9-(2-phosphophenyl methoxyethyl)-adenine; VLCFA, very long-chain saturated fatty-acyl-CoA.

^bOther substrates appear in italics.

MRP4 and MRP5 broaden the spectrum of drug resistance to nucleotide analog drugs; MRP6 plays a role in elastic tissue homeostasis. The functions of MRP7–MRP9 are largely unknown.

Breast Cancer Resistance Protein

BCRP (or ABCG2) is an ABC half transporter that displays drug resistance. In general, the BCRP transporter preferentially extrudes large hydrophobic, positively charged molecules. BCRP is involved in MDR in cancer, especially with regard to acute myeloid leukemia. Also, it plays a role in the survival of stem cells under hypoxic conditions and might play a role in regulating stem-cell differentiation.

Multidrug Resistance Transporter Proteins and Pharmacokinetics

Both the absorption and body distribution of drugs depend on their passage through diverse barriers. A number of MDR transporters limit the absorption of drugs via the gastrointestinal tract and the distribution of drugs into the brain via the blood–brain barrier; excretion is also governed by these transporters.

Oral Absorption

Efflux transporters such as Pgp and the MRPs in the intestinal may form the rate-limiting barrier to oral drug absorption. The poor bioavailability characteristics of many chemotherapeutic agents for cancer and human immunodeficiency virus (HIV) protease inhibitors may be explained by the fact that those drugs are among the best substrates for these transporters. The co-administration of the relevant substrates with the inhibitors/modulators of these transporters is a possible route to enhancing bioavailability. Of interest is the systematic site-specific expression of Pgp and MRPs along the various parts of the gastrointestinal tract.

Brain Distribution

The brain is the tissue most frequently targeted by drugs. To be effective, drugs must be transported to the site of action. The interface between the blood and brain is composed of the blood–brain barrier (brain capillary endothelial cells) and the blood–CSF barrier (choroid plexus epithelial cells).

The presence of these efflux transporters at the blood–brain/CSF barriers explains the fact that many drugs exhibit poor brain distribution despite their favorable lipophilic character; the barriers are substrates for the efflux transporters. Thus, in many studies Pgp, especially (expressed at the luminal face

of the brain capillary endothelial cells), has been shown to be responsible for lowering the brain distribution of many drugs. MRP1 is more specifically localized in the basolateral membrane of the choroid epithelial cells, preventing CSF penetration of its substrates. Pgp is also expressed at the choroid epithelial cells, but in a manner that governs influx transport. Other ABC transporters, such as MRP2 and BCRP, have also been implicated in protecting the brain tissue against exogenous compounds.

Drug Excretion

The liver and kidneys play an important role in the excretion of drugs, the main routes being through the biliary tract and renal proximal tubule, respectively. In both the liver and kidneys, Pgp and other multidrug transporter proteins are variably expressed in the different suborgan structures and cell linings.

Functional Genetic Polymorphism

In addition, functional genetic polymorphisms, as have been identified for the Pgp gene, may influence the absorption, distribution, and excretion of the transporters substrates.

Other Physiological Functions of Multidrug Resistance and Other ATP-Binding Cassette Transporters

The ABC transporters govern a broad spectrum of physiological functions because they are involved in the transmembrane transport of various substances that exhibit a wide variety of chemical structures; examples are endogenous compounds such as ions, amino acids, peptides, sugars, vitamins, steroid hormones, bile acids, and phospholipids and also many exogenous compounds. Next we briefly describe a number of these physiological roles.

Defense against Oxidative Stress, Cancer, and Inflammation

Adequate glutathione (GSH) levels are essential to life and needed to fight infections and cancer cells. The MRPs that have been functionally characterized so far act as ATP-dependent export pumps for conjugates with glutathione, glucuronate, or sulfate. The most important substrate of MRP1 is the endogenous glucuronide conjugate leukotriene C4 (LTC4), a *de novo* synthesized mediator of inflammation. MRP1 and MRP2 also mediate the co-transport of unconjugated amphiphilic compounds, together with free glutathione. MRP3 preferentially transports glucuronides but not glutathione S-conjugates or

free GSH. In addition, MRP1 and MRP2 contribute to the control of the intracellular glutathione disulfide levels and may thereby play an essential role in the response to oxidative stress when the activity of glutathione disulfide reductase becomes rate limiting. Thus, the members of the MRP family serve as export pumps that prevent the accumulation of anionic conjugates and glutathione disulfide in the cytoplasm, and they therefore play an essential role in detoxification and defense against oxidative stress.

Lipid Metabolism

The transport of specific molecules across lipid membranes is also an essential factor in the physiology of all living organisms, and a large number of specific transporters have evolved to carry out this function. Many ABC genes play a role in the maintenance of the lipid bilayer and in the transport of fatty acids and sterols within the body. Actually, the ABCA1 transporter is responsible for delivering cholesterol to nascent high-density lipoprotein (HDL) particles, a process known as reverse cholesterol transport. Enhancing ABCA1 activity, either through changes in gene expression or activity, is a plausible therapeutic strategy for increasing HDL levels. Dietary cholesterol is the primary contributor to the risk of developing cardiovascular disease for a subset of patients. The half-transporters ABCG5 and ABCG8 form a heterodimer responsible for regulating intestinal cholesterol absorption and the excretion of cholesterol in the liver. Increasing ABCG5/G8 expression or activity is a viable strategy for reducing dietary cholesterol. The expression of a large number of ABC transporters in monocytes/macrophages and their regulation by cholesterol flux indicate that these transporter molecules are potentially critical players in chronic inflammatory diseases such as atherosclerosis.

Antigen Presentation

The transporter associated with antigen processing 1 (TAP1; ABCB2) and TAP2 (ABCB3) are half-transporters that serve to transport peptides into the endoplasmic reticulum. At that site, they can be complexed with class I human leukocyte antigen (HLA) molecules for presentation on the cell surface. TAP expression is required for the stable expression of the HLA class I proteins. The TAP complex transports amino acid peptides with a preference for Phe, Leu, Arg, and Tyr at the C-terminus, similar to the specificity of the HLA class I proteins. Several DNA viruses such as herpes simplex virus express molecules that interfere with antigen expression by disrupting the function of the TAP complex. TAP2 (ABCB3) functions as a heterodimer with TAP1.

Regulation of Insulin Secretion

Mutations in ABCC8 may result in familial persistent hyperinsulinemic hypoglycemia of infancy, demonstrating its role in the regulation of insulin secretion. Actually ABCC8 forms ATP-sensitive potassium channel together with an inwardly rectifying potassium channel. The closure of ATP-sensitive potassium channels in pancreatic islet β -cells initiates a cascade of events that leads to insulin secretion. ABCC8 therefore seems to be responsible for regulating glucose metabolism by insulin secretion.

Chloride Secretion

Chloride is the most abundant anion and the predominant permeating species. The chloride channels are crucial for transepithelial transport and the control of water flow, and they often provide unexpected permeation pathways for a large variety of anions. ABCC7 (CFTR, cystic fibrosis transmembrane) is a cAMP-dependent chloride channel and is responsible for chloride secretion in the gastrointestinal mucosa. The major toxins that cause secretory diarrheas act by increasing the levels of cAMP or cGMP. This results in a secondary increase in active chloride secretion through ABCC7, whereas sodium and water follow passively. Compounds that inhibit ABCC7 appear to be well suited as treatments for both secretory diarrhea and cholera.

Potassium Channel Regulation

ATP-sensitive potassium (KATP) channels, as inhibited by intracellular ATP, play key physiological roles in many tissues. KATP channels set membrane excitability in response to stress challenge and preserve cellular energy-dependent functions. ABCC9, together with an inwardly rectifying potassium channel, forms a KATP channel. This complex may have a vital role in securing cellular homeostasis under stress. Mutations in ABCC9 may lead to KATP channel dysfunctions and have been related to susceptibility to dilated cardiomyopathy.

Bile Salt Transport

Canalicular bile secretion is the rate-limiting step in bile formation. The canalicular membrane contains ABC proteins that transport biliary compounds against steep concentration gradients across the canalicular membrane. Pgp excretes hydrophobic cationic compounds, whereas ABCB4 (Pgp3 or MDR3) acts as a phospholipid flippase for phosphatidyl choline. In addition to biliary excretion of phospholipids, bile is also the major pathway for the elimination of cholesterol, mostly derived from HDLs in plasma.

ABCC2 (MRP2) is an important (bilirubin) conjugate export pump. A major liver bile-salt transporter in the liver is ABCB11 (BSEP, bile salt export pump). The production of bile is also critically dependent on the coordinated regulation and function of this BSEP. The endothelin antagonist bosentan inhibits BSEP and leads to the intracellular accumulation of cytotoxic bile salts, and bile-salt-induced liver damage. Similarly, troglitazone, an insulin sensitizer, induces cholestasis and hepatotoxicity via competitive inhibition of the BSEP-mediated bile salt transport.

Multidrug Resistance: ATP-Binding Cassette Transporter Modulation and Regulation of Expression

Modulation

MDR modifying agents, which inhibit the function of the MDR transporters by either competitive or noncompetitive mechanisms, are good candidates for the pharmacological modulation of transporter functionality, currently still mostly focused on cancer treatment. The modulators are intended to increase the cytotoxic action of MDR-related drugs by preventing the extrusion of anticancer drugs from the target cells to significantly improve the treatment effectiveness.

To date, three generations of modulators/inhibitors exist, mostly acting on Pgp. The first generation comprises calcium channel blockers (verapamil, diltiazem, and azidopine), quinine derivatives, calmodulin inhibitors (trifluoroperazine and chlorpromazine), and the immunosuppressive agent cyclosporin A. The modulators of the second generation consists of derivatives of the first-generation compounds, for example R-verapamil and PSC-833 (from cyclosporin). Because of differences in the substrate-specificities and inhibitor-sensitivities of the different MDR proteins expressed in different tumor cells, proper therapeutic intervention requires an advanced diagnosis and targeted modulator agents. The third generation of MDR modifiers was devised to specifically interact with a particular MDR transporter. One example is the reversins, which are small hydrophobic peptide derivatives that are supposed to interact with Pgp with high affinity and selectivity; their clinical efficiency has yet to be proven.

Regulation of Expression

A number of environmental stimuli are known to affect the expression of the Pgp (*mdr1*) genes. In humans, it has been suggested that *mdr1* may function as a heat shock gene and its expression may be

modulated by the numerous agents that trigger these signaling pathways. It seems likely that cellular stress and Pgp expression are closely linked because this transporter plays a crucial role in the protection of cells from toxic products released during environmental stress. More specifically, it has been found that certain steroid hormones enhance Pgp expression. Enhanced expression does not necessarily lead to enhanced efflux functionality because examples also exist of enhanced expression but decreased functionality.

Glossary

Alter

A distinct identity or personality state with its own characteristic and relatively enduring pattern of perceiving, relating to, and thinking about the environment and self. An alter has its own identity, self-representation, autobiographic memory, and sense of ownership of its own thoughts, feelings, and actions. Some synonyms are personality, personality state, subpersonality, alter personality, and dis-aggregate self-state.

Dissociation

“Disruption in the usually integrated functions of consciousness, memory, identity, or perception” (American Psychiatric Association, 2000: 519); the segregation of some subsets of information from other subsets of information in a relatively rule-bound manner (Spiegel, 1986: 123).

Ego state

“An organized system of behavior and experience whose elements are bound together by some common principle but that is separated from other such states by boundaries that are more or less permeable” (Watkins and Watkins, 1993: 278). The creation (or worsening) of a problematic condition as a result of the interventions of a helping professional.

Iatrogenesis

Integration

The unification of all personalities into a single coherent identity; the cessation of separateness of a particular personality or group of personalities; the interventions made by a therapist to bring together two or more personalities at a particular point in time.

Personality

An enduring pattern of behavior, adaptation, and inner experience that is pervasive over time and across situations (in general psychology); synonym for alter (in dissociative disorders).

Resolution

An outcome in which a multiple personality patient has achieved smooth function, continuity of contemporary memory, and the relief of distressing symptoms due to the more facile cooperation and collaboration of the remaining personalities. Some personalities may have integrated.

Shift

A change in the personality system such that while the personality or alter in apparent executive control has not changed or been replaced, it is being influenced by different alters behind the scenes than it had been, leading to minor changes in the appearance, actions, and speech of the alter in apparent executive control.

Switch

A transition from one personality being in apparent executive control to another personality being in apparent executive control.

Introduction

Multiple personality (dissociative identity disorder in the United States) has been described as difficult to understand, difficult to diagnose, difficult to treat, and difficult to discuss objectively not only because of its complexity, but also because of the controversies that often surround it. Its study draws upon the literatures of dissociation, hypnosis, memory, cognitive psychology, social psychology, development, trauma, attachment and psychoanalysis, among others, requiring researchers and clinicians to grapple with concerns and issues that often appear remote and obscure.

History

Conditions in which an individual's customary personality or way of being is replaced by an alternative (and often very different) personality or way of being, whose activities are unknown to the customary personality, were virtually worldwide and commonplace prior to the modern scientific era. Possession states were attributed to the intrusion of various forces, spirits, angels, demons, gods, or ancestors. Judeo-Christian possession states included forms in which the intruding entity took over completely, leaving the possessed person without memory for the intruding entity's actions, and forms in which both customary personality and intruding entity were aware of one another and contended for control (somnambulistic and lucid possession, respectively).

As possession was discredited (circa 1775–1800), cases with these phenomena were reported and described in secular terms (e.g., exchanged identity, doubling of the personality). By the 1830s, French physician Antoine Despine and his physician son and nephew had observed and treated series of such patients. Utilizing contemporary methods and magnetism, a precursor of hypnosis, successful treatments and integrations were achieved. Throughout the nineteenth century there was considerable interest in multiple personality.

However, rising forces in psychiatry and psychology eclipsed its study. Bleuler subsumed multiple personality under schizophrenia. Freud abandoned dissociation for repression. Janet was marginalized by psychoanalysis and the discrediting of his mentor, Charcot. Behaviorism disregarded multiple personality. Within a generation, multiple personality was largely forgotten except as a historical curiosity.

Two books, *The Three Faces of Eve* and *Sybil*, brought multiple personality to the attention of North American readers. A small but increasing number of North American clinicians began to report

numbers of such patients (1970s–80s). Sensitized by feminism and the plight of Viet Nam veterans to the sequelae of abuse for women, children and combat veterans, they understood multiple personality as a chronic posttraumatic dissociative condition. Cases were recognized with increasing frequency. This experience was duplicated in The Netherlands and elsewhere.

In the 1990s there were highly polarized debates about whether multiple personality was iatrogenic, instigated and sustained by clinicians' interest in motivating patients to demonstrate the condition's phenomena, and whether the abuses alleged by patients, often recalled after years of apparent amnesia, were false, suggested by leading questions or subtle expressions of interest.

It remains unclear whether multiple personality can be created by iatrogenic factors alone. Some reports indicate that efforts to create conditions similar to multiple personality have been undertaken by various intelligence agencies. Some social psychology manipulations can cause subjects to demonstrate some characteristics of multiple personality under experimental conditions. However, no evidence demonstrates that clinicians exert influences similar to the interventions of either covert agencies or laboratory experiments. While some individuals are subject to develop false memories, many memories that became available after long absence from awareness have proven accurate.

Definition and Characteristic Findings

Criteria

The American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision (DSM-IV-TR) offers four diagnostic criteria for dissociative identity disorder (multiple personality) (Table 1).

Phenomena

Multiple personality involves problems with identity, memory, thinking, containment, cohesive conation, and the switch process. Problems of identity may include the presence of other identities (alters), depersonalization, an absence of or confusion about identity, alters' impingements on one another, and the combined presence of two or more alters. Problems of memory may include amnesia for past events, losing blocks of contemporary time, uncertainty about whether events did or did not occur, fragmentary recall, and experiencing events as dream-like, unreal, or of uncertain reality. There are often amnesia barriers across the alters, which may be aware or

Table 1 DSM-IV diagnostic criteria for dissociative identity disorder^a

- A. The presence of one or more distinct identities or personality states (each with its own relatively enduring pattern of perceiving, relating to, and thinking about the environment and self).
- B. At least two of these identities or personality states recurrently take control of the person's behavior.
- C. Inability to recall important personal information that is too extensive to be explained by ordinary forgetfulness.
- D. The disturbance is not due to the direct physiological effects of a substance (e.g., blackouts or chaotic behavior during alcohol intoxication) or a general medical condition (e.g., complex partial seizures). Note: in children, the symptoms are not attributable to imaginary playmates or other fantasy play.

^aFrom the American Psychiatric Association (2000), p. 529. Reprinted with permission from the Diagnostic and Statistical Manual of Mental Disorders, Copyright 2000. American Psychiatric Association.

unaware of one another or display directional amnesia. In directional amnesia, alter A may know about alter B and be aware of B's thoughts and activities, while B knows little or nothing about A, is unaware of A's thoughts, and has no recall of what happens when A is in control.

Problems of thinking include cognitive errors, magical thinking, and the toleration of mutually incompatible ideas and perceptions without appreciating the impossibility of their coexisting (trance logic). They stem from distortions of reality made to accommodate to intolerable childhood circumstances.

Problems of containment include the intrusions of alters into one another and leakage of the memories, feelings, and sensations of one alter into the awareness and experience of another.

Problems of cohesive conation (will and intentionality) refer to difficulties in the distribution of executive control across the alters. Patients' sense of control of themselves and their actions may be compromised, along with their sense of ownership, responsibility, and voluntary control of themselves and their actions.

Problems of the switch process refer to changes of executive control that are jarring, incomplete, or so frequent that the person cannot concentrate or pay attention consistently enough to accomplish necessary functions and tasks.

Personalities

Personalities, personality states, subpersonalities, personifications, self-states, and alters are synonyms. They are relatively stable and enduring entities with fairly consistent ways of perceiving, relating to, and thinking about the environment and self. They are experienced as having their own identities,

self-images, personal histories, and senses of ownership of their own activities and mental contents. Personalities usually but not inevitably have names. Some names may refer to attributes or emotions or humiliating insults. Usually a rather passive, guilt-ridden, dependent, masochistic, and depressed personality in apparent control most of the time bears the legal name. Alternate personalities may differ in name, age, race, gender, sexual orientation, areas of knowledge, predominant affect, vocabulary, and apparent intelligence. Alters may or may not be aware of one another. Alters may relate to one another in a potentially complex inner world. They constitute ongoing sets of parallel processes; that is, as one alter is dealing with the outside world, another may be making comments on or to the first, while others are interacting with one another, oblivious to external events. Neuropsychophysiological studies often demonstrate significant differences in different types of personality.

Personalities arise as desperate coping strategies, initially serving adaptive and defensive purposes. Achieving a degree of autonomy and persisting beyond the situations to which they were responses, they may become increasingly problematic and disruptive. Alters are formed by repudiating a sense of self and a representation of self in interactions with others that have become intolerable, severing empathic connection and erecting boundaries between the self that has become intolerable and a more adaptive identity created to manage the adaptation believed to be required. This new alter, envisioned and experienced as real, is accepted and interpreted as real. Its alternate autobiographic memories are endorsed as real.

For example: Lois, a 5-year-old girl, is molested by her previously warm and loving Uncle Ben. She is deeply attached to her uncle and does not want to lose him, afraid of the consequences of telling her parents, confused about the feelings and sensations arising in her, wishing this molestation had never occurred, and wanting someone to rescue her. [Table 2](#) illustrates numerous coping strategies and alters that might be created to embody them. Strategies strongly influence the transformations of identity and autobiographic memory that alters will embody. For example, Bad Lois must repudiate knowledge that would demonstrate that Lois is an innocent victim. Louis not only must disregard attributes and experiences that would compel him to acknowledge he is a little girl, but also may need to hallucinate having a male body with appropriate musculature, facial hair, and genitalia.

Alters often experience themselves as having relationships with one another in an inner world that

Table 2 Coping strategies and alter formation of 'Lois'^a

<i>Cognitive coping strategy</i>	<i>Alter created</i>
This did not happen	A Lois who knows, and a Lois who does not
I must have deserved it	Bad Lois, whose behavior would explain trauma as punishment
I must have wanted it	A sexual alter, Sherrie
I can control it better if I take charge	An aggressively sexual alter, Vickie
I would be safe if I were a boy	Louis, Lois' male twin
I wish I were a big man	Big Jack, based on some person of power who could prevent this
I wish I were the one who could hurt someone and not be hurt	Uncle Ben, or a more disguised identification with the aggressor
I wish I could feel nothing	Jessie, who endures all yet feels nothing
I wish someone could replace me	The Girls, who encapsulate specific experiences of trauma unknown to Lois
I wish someone would comfort me	Angel, with whom Lois imagines herself to be while the body is being exploited and the Girls are experiencing the trauma

^aFrom Kluft (1999), p. 5.

may be experienced as possessing reality and importance that is equally or more compelling than the external world. Inner world events may be reported as if they had occurred in external reality, and vice versa.

Comorbidity

Multiple personalities commonly suffer additional mental disorders. It may be difficult to be sure whether the diagnostic criteria for some of these other disorders are satisfied by symptoms emerging from multiple personality or whether they indicate co-occurring diagnoses that require treatments of their own. Posttraumatic stress disorder, major depression, various substance abuses, borderline personality disorder, other anxiety and affective disorders, somatoform disorders, sexual dysfunctions, eating disorders, and other personality disorders commonly co-occur. Symptoms of another disorder may be found in all or most of the personalities, but sometimes only in particular personalities. Distinguishing between comorbidities and look-alike epiphenomena can prove challenging.

Prognosis may be determined more by the treatability of comorbid conditions than by the multiple personality. For example, a multiple personality with posttraumatic stress disorder and a depression that responds well to medication has a much better prognosis than one with posttraumatic stress disorder, anorexia nervosa, rapid-cycling bipolar disorder, and borderline personality disorder.

Etiology

The predominant theory of the etiology of multiple personality holds that this condition comes into being when a child with high hypnotic potential and problematic support from caretakers and/or attachment issues experiences overwhelming traumatic stress, usually on a repeated basis, and is not protected,

comforted, and supported in a way that alleviates the child's distress. The iatrogenesis hypothesis was noted previously. Many scholars consider both alternatives plausible and do not assume that either precludes the possibility of the other.

Data consistent with the predominant theory include the high hypnotizability of this patient group, documentation of abuse in 95% of two cohorts of young dissociative patients, and epidemiological studies in many nations using reliable and valid screening and diagnostic instruments finding a similar incidence of multiple personality (4–6% of psychiatric inpatients) in many nations with very different degrees of awareness of and sympathy toward the diagnosis of multiple personality. If clinicians with special interest in multiple personality act in such a way as to create it, an assumption of the iatrogenesis hypothesis, significantly higher percentages should be encountered in countries in which clinicians are accused of applying such pressures.

Observations consistent with the iatrogenesis hypothesis are the development of transient multiple personality-like phenomena in laboratory settings, reports of the creation of artificial multiple personality by intelligence agencies, and the fact that multiple personality patients have been known to create additional personalities in response to therapists' suggestions. Those most experienced with multiple personality hold that multiple personality cannot be created by therapists under normal clinical circumstances, but that additional personalities can be created in response to perceived pressures from a therapist.

Diagnosis

It was long thought that multiple personality was rare and sufficiently flamboyant to make its presence self-evident. Multiple personality has proven to be far

from rare, usually covert, and commonly misdiagnosed for an average of 6.8 years. With the demonstration of widespread false negative diagnoses, diagnostic efforts were accorded greater importance.

The Natural History of Multiple Personality

While a small percentage (6%) of adult multiple personalities are florid and overt most of the time, the vast majority either take pains to avoid drawing attention to their situations and/or have only windows of overtness, usually in the context of psychosocial stress or encountering situations that in some way are analogous to overwhelming childhood events or that force them to contend with an abusive figure from their childhood (or someone who is perceived as similar to such a figure). Usually personalities either are relatively quiescent or exert their influence from behind the scenes by shifting or intruding into or otherwise influencing (by persuasion or threat) the personality in apparent executive control. They may contrive to pass as the usually apparent personality.

Multiple personality usually is clandestine in children and difficult to distinguish from various turmoils and early manifestations of psychotic disorders in adolescents. Young adults often work to avoid detection and deny manifestations of the condition. As individuals mature, they usually enter a complex matrix of work, family, and relationships and are less closely connected with important figures of their childhood. Less immediately pressured to keep childhood issues out of awareness and increasingly experiencing situations that are related to or analogous to childhood experiences (including intercurrent adult trauma), they often become symptomatic and seek treatment for what appears to be anxiety or depression. Treating clinicians may recognize or suspect dissociative phenomena.

Diagnostic Approaches

Considering the usually covert nature of multiple personality, it cannot be assumed that it will declare itself in typical clinical interviews or mental status examinations, or even in therapy sessions. Clinicians have derived lists of suggestive signs of multiple personality. Experience-derived suggestive signs include common findings in multiple personalities' histories and indications of dissociated behavior (i.e., having been given many different diagnoses, being told by others of disremembered out-of-character behavior, finding objects, productions, or writing in one's possession that one cannot recall acquiring or creating). Loewenstein developed a mental status that studies six relevant symptom clusters: (1) indications of

multiple personality processes at work (e.g., differences in behavior, linguistic indications, switching/shifting); (2) signs of the patient's high hypnotic potential (e.g., enthrallment, trance logic, out-of-body experiences); (3) amnesia; (4) somatoform symptoms; (5) posttraumatic stress disorder symptoms; and (6) affective symptoms.

Instruments have been developed to screen patients for dissociative phenomena; high scores or particular patterns of response suggest that further evaluation is needed. Structured diagnostic interviews have enabled actual diagnostic assessment. The most well-known of these are the Dissociative Experiences Scale (Bernstein and Putnam) for screening and the Structured Clinical Interview for the Diagnosis of DSM-IV Dissociative Disorders – Revised (Steinberg) for diagnostic purposes.

Differential Diagnosis

The differential diagnosis includes other dissociative disorders, psychotic disorders, affective disorders, borderline personality disorder, partial complex seizures, factitious disorders, and malingering. Evaluators knowledgeable about all of these disorders usually find differential diagnosis to be straightforward. Evaluators unfamiliar with dissociative disorders commonly encounter difficulties because phenomena of many of these conditions overlap.

Treatment

Approaches and Modalities

Treatment resembles a stage-oriented trauma therapy, modified to include work with alters. However, work with some alters and issues may be quite advanced and work with others may be just beginning while still others have not yet been discovered. The treatment may be understood as a series of short-term therapies imbricated within the process of a long-term psychotherapy. Virtually every therapeutic model and modality has been applied to multiple personality. In practice, advocates of different theoretical models and treatment approaches find themselves making many similar interventions. In successful treatments, the pragmatic realities of dealing with multiple personality tend to determine what is done.

Treatment Stages

In the three-stage model of modern trauma therapy outlined by Herman, a phase of safety, in which the patient receives sanctuary and support and is strengthened, is followed by a phase of remembrance and mourning, in which the mind's representation of

its traumatic experiences is explored, processed, and mastered and in which the losses and consequences associated with traumatization are grieved. The mind is reintegrated, and roles and functions are resumed in a phase of reconnection.

In the nine-stage treatment of multiple personality (Kluft, 1999a,b) with multiple personality (1) the psychotherapy is established and (2) preliminary interventions are made to establish safety, develop a therapeutic alliance that includes the alters, and enhance the patient's coping capacities. Then follows (3) history gathering and mapping to learn more about the alters, their concerns, and how the system of alters functions. Then is it possible to begin (4) the metabolism of trauma within and across the alters. As the alters share more, work through more, communicate more effectively with one another, and achieve more mutual awareness, identification, and empathy, their conflicts are reduced, as is contemporary amnesia. They increasingly cooperate and experience some reduction of their differences and senses of separateness. This is called (5) moving toward integration/resolution. More solidified stances toward one's self and the world are reached in (6) integration/resolution. Smooth and functional collaboration among the alters, usually including the blending of several personalities, is called a resolution. Blending all alters into a subjective sense of smooth unity is an integration. Then the patient focuses on (7) learning new coping skills, working out alternatives to dissociative functioning, and resolving other previously unaddressed concerns. Issues continue to be processed, and mastery without resort to dysfunctional dissociation is pursued in (8) solidification of gains and working through. Finally, treatment tapers, and the patient is seen at increasingly infrequent intervals in a stage of (9) follow-up.

Typical Issues

Treatment may prove arduous and challenging to patient and therapist alike. Work with traumatic material can be upsetting and destabilizing. Worse than the material itself is the pain of integrating what patients learn into their perceptions of their relationships with significant others who may appear to have been perpetrators of previously unremembered mistreatment. This is complicated by the fact that it is usually not possible to either validate or invalidate most of the traumatic memories that emerge. Patients should be informed about the possibility that material that emerges and may be useful for treatment may not prove to be accurate.

Processing traumatic memories has been controversial because the accuracy of initially unavailable

memories has been challenged and the affects experienced in association with this processing may cause upset and trigger self-destructive impulses. Occasionally decompensation occurs. Some multiple personalities cannot tolerate such work. However, thus far, reported successful recoveries to the point of integration have involved processing traumatic memories. Studies have demonstrated that many recovered memories of multiple personality patients have been confirmed, and some have been proven inaccurate. Current opinion suggests that deliberate processing of traumatic memories should not proceed unless patients have demonstrated adequate strength and stability for such work. All others should be treated supportively, addressing traumatic memories only when they are intrusive, are disruptive, and cannot be put aside.

Patients typically have periods of wanting to disavow everything said in therapy, trying to banish painful memories of trauma, betrayal, and loss associated with important people in their lives in order to retain relationships and a sense of safety within those valued relationships. Tact, containment, and circumspection are required from therapist and patient alike. The patient should be protected from becoming overwhelmed by and lost in the traumatic material, and treatment should be paced to safeguard the patient's safety and stability. All pressures to get everything out and over with must be resisted.

The alter system is designed to facilitate escape from pain and difficulty or, failing that, to reframe or disguise it. Alters often reenact scenarios that (in their perceptions) are tried and true methods of keeping pain at bay, even if they disrupt the patient's treatment, life, and relationships. Containing and/or minimizing such events is an ongoing challenge to the treatment, rarely completely successful until therapy is well advanced.

Some have advised against working with alters lest separateness be reified and reinforced by their being addressed directly and individually, and recommend speaking in ways that always convey that the patient is a single person. In practice, working directly with alters often may make them more prominent transiently, but as they are worked with, empathized with, and helped to communicate with other alters, their separateness is eroded. All published series of successful integrations have been contributed by authors who work directly with alters.

The therapist should treat all of the personalities with respect, simultaneously appreciating the immediacy, forcefulness, and defensive aspects of their entrenched and subjectively compelling senses of separateness, and that all express aspects of a single

individual, whose personality structure is to have multiple personalities. Interventions to contain alters' dysfunctional behaviors, aggressiveness toward other personalities, self-destructiveness, and irresponsible autonomy (e.g., failing to care for children, who may be seen as belonging to another personality) may prove necessary. The therapist may call upon personalities to work on their particular issues in the treatment and to facilitate their cooperation with the treatment and one another.

Treatment must respect the entirety of the patient's concerns. Specific multiple personality treatment may be deferred repeatedly to address pressing concerns and other mental health issues. For example, a woman with multiple personality whose child develops cancer is not in a position to pursue trauma work.

Patient Subgroups

Some multiple personality patients cannot achieve the goals of the early stages of treatment and move on to process traumatic events and bring personalities together. Those with severe comorbidity and maladaptive character issues may never achieve enough stability to follow that path. Their treatment will involve ongoing efforts to enhance safety and strength and will defer trauma work unless material is intrusive and unavoidable. Therapy prioritizes better coping strategies and enhanced cooperation among alters. An intermediate group will go through phases in which trauma work can be done and phases in which it cannot be tolerated. Therapists should be flexible and err on the side of caution whenever uncertain about the safety of trauma work.

Hypnosis

Multiple personality is associated with high hypnotizability, a stable trait. Hypnosis may occur because a clinician performs an induction procedure, because an individual induces self-hypnosis, or because spontaneous trance is triggered by some stimulus or activity, such as strong emotion or meditation. Therefore, therapists cannot control whether hypnosis occurs in the course of a therapy. Bearing this in mind, therapists should avoid making remarks that might suggest that particular events have taken place or that particular persons were involved in doing harmful things, because they may be heard as powerful hypnotic suggestions.

Notwithstanding such concerns, hypnotic interventions can play a major role in stabilizing multiple personality patients, managing abreactions, containing powerful emotions, accessing alters for therapeutic work, and promoting integration.

Miscellaneous Concerns

Forensic Aspects of Multiple Personality

The relevance of multiple personality as a defense varies tremendously depending upon (1) diverse requirements for the insanity defense in different jurisdictions and (2) the phenomenology in particular multiple personalities. Criminal acts may have taken place because of the impact of multiple personality upon a person's capacity to know his or her own mind and control its various aspects, without thereby satisfying legal definitions of insanity.

The assessment of defendants claiming to have or thought to have multiple personality should proceed with a keen eye toward discerning both factitious and malingered presentations, informed by a state-of-the-art knowledge of multiple personality drawn from the modern clinical literature.

The Impact of Controversy

Controversy magnifies the burden of having, treating, or researching multiple personality. Multiple personality patients must contend with the impact of efforts to deny the reality of their condition and the credibility of what they believe to be their autobiographic memories, attacks on the competence and credibility of those who treat them, and criticism and rejection from those who believe, either accurately or inaccurately, that the multiple personality patient is revealing their secrets or making scandalous accusations against them or those they love in treatment. Therapists treating such patients must contend with ongoing questioning of their efforts, methods, and intentions and accusations that they are encouraging iatrogenesis and confabulated false memories. Researchers have difficulty obtaining funds to expand our knowledge of this condition and may be endangering the trajectory of their careers by working in this area.

Concluding Remarks

Notwithstanding the complexity and difficulty associated with multiple personality, this disorder often proves treatable to a satisfactory outcome and offers unique insights into the impact of overwhelming stressors upon human memory and identity and into the neuropsychophysiology of mental structures and functions. It is moving into the mainstream of the mental health professions and should be of concern to all mental health professionals.

Glossary

Cytokine A protein secreted by the immune cells that affects immune responses.

Experimental allergic encephalomyelitis (EAE)

An autoimmune disease caused by the injection of brain proteins (myelin oligodendrocyte protein, MOG; proteolipid protein, PLP; myelin basic protein, MBP); in some ways, a model of multiple sclerosis.

Human leukocyte antigen (HLA) Interferon (IFN)- γ

A protein on the membrane of most cells that is recognized by immune cells.

A cytokine secreted by lymphocytes that is involved in Th1 immune responses. Treatment with this IFN causes exacerbations of multiple sclerosis.

Oligoclonal bands

Immunoglobulin G of restricted heterogeneity, which forms several discrete bands on electrophoresis of cerebrospinal fluid. Myelin-forming cells of the central nervous system.

Oligodendroglia Plaque

Inflammatory and scarred (gliosis) central nervous system lesions in multiple sclerosis.

T helper 1 (Th1) cells

T helper lymphocytes that secrete IL-2 and IFN- γ and mediate delayed-type hypersensitivity immunity.

T helper 2 (Th2) cells

T helper lymphocytes that secrete IL-4 and IL-10 and amplify humoral immunity.

Ask a roomful of multiple sclerosis (MS) patients whether MS attacks are caused by stress, and 9 out of 10 will say “of course.” However, objective and quantitative measurement is difficult for both MS exacerbations and stress. Could stress affect immunity and could immune changes in turn affect MS? More important, does stress directly affect MS?

Multiple Sclerosis – Overview

Multiple sclerosis is a disease caused by intermittent perivenular inflammation of areas of the central nervous system (CNS). These plaques affect every function controlled by the brain and spinal cord.

MS usually appears between the age of 20 and 50, in women twice as often as men, and is most common in people of northern European ancestry. A complex interaction of multiple genes and the environment may lead to MS. HLA-DR2 predisposes to MS in northern Europeans, but other HLA types are linked to MS in Sardinia, Turkey, and the Middle East. MS is more common in areas far from the equator. Migration studies suggest that an environmental influence before puberty also affects the development of MS. Viruses are the main environmental culprits, but no single virus has been convincingly linked to MS.

Three factors consistently increase MS exacerbations: (1) virus infections (there may also be some effect of prostate, bladder, and sinus infections, which provoke MS symptoms and possibly cause exacerbations), (2) delivery of a baby (there are more exacerbations during the several months postpartum than during pregnancy), and (3) IFN- γ (injections of IFN- γ causes a fourfold increase in MS flares).

Immune Abnormalities in Multiple Sclerosis

The immune system is abnormal in MS. Inflammatory cells destroy oligodendroglia and some neurons in MS plaques. Macrophages far outnumber lymphocytes in these lesions. The inflammation in brain tissue is reflected by small numbers of activated immune cells in the cerebrospinal fluid (CSF; T cells outnumber B cells and macrophages in CSF) and excessive levels of immunoglobulins (IgG; seen in oligoclonal bands). Some T cells and some antibodies recognize virus or brain antigens (myelin oligodendrocyte protein, MOG; proteolipid protein, PLP; myelin basic protein, MBP; heat shock proteins; S-100 protein; and α B-crystallin), but most recognize other targets (e.g., nonsense antibodies). Cytokines in the CSF such as tumor necrosis factor (TNF)- α and interleukin (IL)-6 correlate with disease activity and blood–brain barrier (BBB) damage. In culture, very high doses of IFN- γ and

TNF- α kill oligodendroglia; at lower doses, TNF- α still interferes with oligodendroglial function.

The peripheral blood is also abnormal in MS. Changes in the blood sometimes precede clinical attacks. Several weeks before exacerbations, mitogen-activated white blood cells secrete excessive amounts of IFN- γ and TNF- α , and lymphocytes show more IFN- γ -induced $[Ca^{2+}]_i$ influx. All of these peripheral immune changes could amplify the antibrain immune response.

During attacks, suppressor cell function drops, IL-12 increases and is likely to induce IFN- γ , and expression of the costimulatory CD80 (B7.1) protein increases on lymphocytes. These changes may lead to antibrain immune reactions. Treatments for MS partially reverse immune abnormalities, and reduce exacerbations by 33%. Interferon-beta reduces inflammatory cytokines, increases suppressor cell function, and prevents immune cells from entering the brain. Glatiramer acetate shifts cells from pro-inflammatory (Th1) to anti-inflammatory (Th2) immunity. Both agents may also induce neurotrophic factors in lymphocytes.

Neuroendocrine and Sympathetic Nervous Systems in Multiple Sclerosis

There are other abnormalities in MS possibly linked to stress responses. MS and Crohn's disease occur together more often than expected. Both are relapsing/remitting diseases with possible viral/bacterial triggers, show similar immune abnormalities, and have anecdotal links to stress. However, typical autoimmune diseases such as systemic lupus erythematosus are not linked to MS.

There is an increased incidence of depression in MS patients and possibly in their families. The diagnostic laboratory test for depression – the dexamethasone suppression test – is abnormal in active MS, at least as often as in depression.

Some patients have elevated cortisol and enlarged adrenal glands. Steroids do not inhibit proliferation and do not induce glucocorticoid receptor translocation in MS lymphocytes compared to normal lymphocytes. Responses to corticotropin releasing hormone (CRH) are normal, but arginine vasopressin (AVP) stimulation of the pituitary is subnormal. These abnormalities may all be a consequence of chronic high cortisol levels caused by stress or inflammation, which could change the set point for steroid responses. (Rats susceptible to EAE have similar neuroendocrine abnormalities; EAE-sensitive strains are less responsive to steroids.)

Glucocorticoid therapy curtails acute inflammation in MS plaques. Steroid therapy may correct the

abnormal endogenous glucocorticoid feedback that otherwise allows unchecked immune responses. As a corollary, some MS patients may need higher levels of steroid therapy than normal subjects to inhibit immune functions. Note that a sudden drop in steroid levels may enhance immunity.

The sympathetic nervous system (SNS) is abnormal in MS, especially in patients with progressive disease. MS patients with progressive disease often have cold purple legs, reflecting decreased control of blood vessel tone. These patients have diminished R-R wave variation on an electrocardiograph (EKG) during inspiration and reduced sympathetic skin responses. This response is a sympathetic discharge after a peripheral stimulus. All these abnormalities are likely to be from a loss of sympathetic control caused by MS plaques in the spinal cord.

The SNS innervates immune organs. The loss of sympathetic tone may have consequences for the immune system in MS. When nerves are cut, the target tissue develops denervation supersensitivity to the relevant neurotransmitter. In MS, β -adrenergic receptors (β -AR) and responses to adrenergic agonists (which induce cAMP) are increased in CD8⁺, CD28⁺ T lymphocytes (suppressor T cells). These cells are responsible for the reduced concanavalin A-induced suppressor function seen during the exacerbations and progression of MS. Stress elevates catecholamines and could theoretically destabilize immune regulation if MS lymphocytes were overly sensitive to adrenalin.

Muscarinic receptors are increased on CD4⁺ lymphocytes (T helper cells). Vagal output could potentially affect the development of thymic tolerance or activate T helper cells. Stress effects on the parasympathetic nervous system are not well studied.

Stress Inhibits Experimental Allergic Encephalomyelitis

Immunization with brain proteins (MBP, PLP, and MOG) causes autoimmune EAE in one animal model of MS. Some stress effects on EAE could therefore be instructive. However, the murine immune system has significant differences from the human immune system, the initial antigenic trigger in MS is unknown, and some drugs have completely opposite effects in EAE and MS. For these reasons, the effects of stress in EAE may not always correspond to the effects in MS.

Glucocorticoids suppress EAE. Merely picking up a rat ameliorates EAE. Handling stress triggers a surge of corticosterone, the rat homolog of human cortisol. Restraint stress also suppresses acute EAE, but it does not affect established EAE. In parallel with these

endogenous steroid effects, treatment with dexamethasone markedly inhibits all stages of EAE. Extending these data to humans suggests that stress should inhibit MS. Anecdotal reports that MS improves after skydiving fit into this line of thought, but remain anecdotes.

When stress is stopped, there is a rebound of severe inflammation in EAE. Similarly, if the dexamethasone used to suppress EAE is suddenly withdrawn, rats develop very severe disease within 5 days. This rebound worsening is seen following a 3-day pulse of dexamethasone even in rats that have recovered from EAE. A pulse of high-dose steroids is a standard treatment for MS exacerbation, yet clinical rebound is seldom seen in MS. Again, EAE differs from MS.

Catecholamines also inhibit EAE through β_2 -adrenergic receptors on lymphocytes. Terbutaline, a β_2 -adrenergic agonist; misoprostal, a prostaglandin E analog; and pentoxifylline, a phosphodiesterase III inhibitor, all elevate cAMP. These agents increase levels of cAMP in lymphocytes, inhibit Th1 responses, and reduce EAE severity.

Could Stress Affect Immune Function?

Stress appears to inhibit the immune system. After intense studying for final exams, medical students are more likely to develop upper respiratory tract infections. Similarly, bereavement (loss of a loved one), divorce, caring for a spouse with Alzheimer's disease, and surgery for breast cancer are associated with excess infections and decreased *in vitro* immune function.

Acute stress and chronic stress both affect immunity. Acute stress causes a rise in serum catecholamines and cortisol; these suppress immune function and also affect immune cell distribution and trafficking. Chronic stress enforces the hypothalamic AVP response to stress, but reduces steroid responses, and so may increase cellular immunity. Products of this stress response affect immunity. Agents that elevate cAMP in lymphocytes inhibit EAE. When used to treat MS exacerbations, glucocorticoids speed up recovery from exacerbations but have no long-term benefit. Steroids cause apoptosis of T cells that are in contact with astrocytes in inflammatory sites. This argues that stress should prevent MS exacerbations. However, although terbutaline does decrease fatigue, treatment of MS patients with cAMP elevators has no significant effect on disease activity.

Two factors could boost immune function after stress. A rebound in immune function is possible after stress is withdrawn. Second, virus infections appear to trigger MS exacerbations. One of three upper respiratory tract infections is followed by an

MS flare, possibly because viruses induce IFN- γ and other inflammatory cytokines. It therefore seems logical to invoke a chain of events that ultimately cause attacks of MS – stress, immunosuppression, virus infection, and then an exacerbation of MS.

Do Neurosurgical Lesions or Physical Trauma Incite Multiple Sclerosis Plaques?

Theoretically, direct trauma to brain tissue damages the BBB and could be a nidus for an MS plaque. Stress, frequently associated with surgery or injury could also potentially affect inflammation at the site of trauma. What is the evidence?

One to 2 days after direct trauma to a rat brain or spinal cord, mononuclear cells invade the damaged area. Seven days after injury, lymphocytes isolated from lymph nodes induce adoptive-transfer EAE. At later times, lymph node cells are not encephalitogenic, indicating that endogenous suppressor mechanisms prevent further immune reactivity to the brain. Thus, there is a critical period following trauma when immune cells are predisposed to attack the brain. A critical period is more difficult to define in MS, but some studies have looked at exacerbations during the period following trauma.

EAE is prone to develop at an electrolytic lesion – damage to the BBB, heat (releasing heat shock proteins), hemorrhage (including white blood cells), and inflammation are potential mechanisms. Moreover, trauma can induce diffuse changes in the brain. At 4–7 days after trauma, the BBB becomes leaky in the gray matter contralateral to the insult.

Early reports suggested that trauma caused the onset of MS. Contrary to a few case reports, anesthesia or spinal taps do not trigger attacks of MS. Most experts now believe that there is no convincing connection between trauma and exacerbations of MS. There remains some debate, although it mainly takes place in courtrooms.

MS plaques are twice as frequent in the cervical spinal cord as other cord sites. It has been argued that flexion and extension of the neck stretch the cord and predispose to MS lesions. Some also suggest that the effect would be more pronounced at the level of a herniated disk. All of these arguments are irrelevant in the thoracic area, which is only slightly mobile compared to the cervical cord and is infrequently the site of herniated disks. The thoracic cord is a relatively frequent site of MS lesions, but is thinner than the cervical cord so the number of plaques per gram of tissue is not so different. A related condition, transverse myelitis, is actually more common in the thoracic area. Because two diseases can have additive effects, the removal of a symptomatic disk

in an MS patient can decrease some neurological symptoms.

Direct trauma to the CNS under controlled conditions was studied in MS patients with severe tremors. In the 1970s, several patients treated with thalamic ablation developed MS plaques along the needle track. Other patients, however, had similar surgery but had no lesions along the track. More recent treatment of tremor with thalamic lesions or stimulation has not been reported to cause MS plaques. The discrepancy between old and new studies may lie in the neurosurgical technique. Hot electrodes could generate heat shock proteins (B. G. W. Amason, personal communication), which cross-react with MBP. However, the older studies were anecdotal and at the time imaging was nonexistent; plaques may have been present before the needle was inserted.

The biopsy of a large, active MS plaque should be a provocateur of nearby inflammation. As with other recent neurosurgical procedures in MS patients, there are no reports of biopsies being followed by exacerbations.

Does Stress Cause Multiple Sclerosis? Actual Data from Multiple Sclerosis Patients

All the arguments described so far suggesting that stress and immunity cause MS exacerbations, are theoretical. The only way to resolve these speculations is through controlled studies of the effect of stress on the course of MS.

There is a large literature on the effect of physical and psychological stress on MS. In one of the first recorded cases of MS, Augustus d'Este wrote in 1822 (Murray 2005) that decreased vision followed the funeral of “a relative for whom I had the affection of a son.” Much of the early literature is anecdotal or is based on retrospective, uncontrolled studies.

MS symptoms are intermittent, have highly variable severity, and involve disparate areas of the nervous system. Moreover, even without new active inflammation, MS symptoms can be mimicked if old subclinical lesions are compromised. Elevation of body temperature, external heat or humidity, and infections (e.g., upper respiratory, urinary tract, lung, prostate) lower the safety factor for electrical impulses along a nerve and amplify the prior loss of function in plaques. There are also many patient reports of acute worsening with menses, anxiety, stress, fatigue, malaise, and depression. Thus, various forms of stress could make MS symptoms worse without changing immunity or immune function.

These pseudoexacerbations are likely to confound the clinical exam and history of true MS

exacerbations. MS symptoms are also quite subject to selective memory in the patient's search for the cause of the exacerbation. The best way to examine any connection between stress and MS is with controlled prospective studies by investigators with extensive MS experience. Only a few have been performed.

For example, in controlled prospective studies Sibley and Siva showed that emotional stress is not linked to MS exacerbations. They also found no convincing link between physical trauma and MS exacerbations. Buljevac and Ackerman reported a link, but recall bias may have contributed to this result. Severe stress, such as gunshot wounds and SCUD missile attacks, actually seemed to reduce exacerbations.

Medical-Legal Implications

Stress or trauma often coincides with MS exacerbations. Trauma to the brain can cause CNS dysfunction, and it is often difficult to sort out whether trauma or MS is responsible for a given symptom. Moreover, stress or trauma could amplify the effects of prior MS lesions. Confounding factors such as elevated temperature, infections, and fatigue could also intensify MS symptoms.

Some argue that in some patients, at some times, stress could modify immunity and possibly trigger attacks of MS. However, this position is highly speculative and probably wrong in a disease with very complex clinical symptoms. There is no clear evidence that stress or trauma causes the onset of MS or that stress or trauma triggers attacks of MS.

Posttraumatic Psychological Complications

Glossary

<i>Hemorrhagic shock</i>	Significant acute blood loss leading to hypovolemia and hypotension.
<i>Open fracture</i>	A compound fracture with an open wound down to the bone; usually associated with severe vascular impairment.
<i>Posttraumatic stress disorder (PTSD)</i>	The development of characteristic symptoms after a traumatic event, including numbed responsiveness to stimuli, autonomic and cognitive dysfunction, and dysphoria.

Multiple Trauma: Background

In most Western societies, traumatic injuries represent the third leading cause of death after cardiovascular diseases and tumors. Of the accidents that occur, approximately 60% take place at home or during sport activities, 27% take place at work, 9% are related to traffic accidents, and approximately 4% are the result of violent actions. However, of the polytraumatic injuries, over 70% are attributed to traffic accidents, followed by accidents at home (20%) and work (10%). More than one-half of the patients with multiple trauma have fractures, dislocations, or both.

In the polytrauma patient, the management of orthopedic injuries can have profound effect on the patient's ultimate functional recovery and may be life- or limb-saving. Life- and limb-threatening musculoskeletal problems include hemorrhage from wounds and fractures, infections from open fractures, limb loss from vascular damage and compartment syndrome, and loss of function from spinal or peripheral neurological injuries. The frequency of

pulmonary complications, adult respiratory distress syndrome (ARDS), fat emboli, and pneumonia has been correlated to the timing and type of treatment of long bone fractures, with a statistically significant increase in morbidity, pulmonary complications, and length of hospitalization when stabilization of a major fracture was delayed. Consequently, since the early 1990s, emphasis has been on early total care of multiply injured patients, including fracture stabilization.

Multiple trauma injuries are frequently complicated with open fractures. Open fractures types IIIB and IIIC are extremely severe injuries that often may lead to limb amputation. These fractures are usually caused by a high-energy impact that results in extensive bony comminution or segmental bone loss, pronounced soft tissue injury including extensive skin loss, tendon and nerve damage, muscular and periosteal stripping from the bone (type IIIB), and severe circulatory compromise of the extremity related to the complete ischemia produced secondary to trauma of the major vessels (type IIIC).

The incidence of amputation rate of type IIIC fractures ranges from 60 to 100%. The aim today is not just to salvage the limb that has sustained this compound injury but to produce a functional painless extremity with at least protective sensation. Several variables play a decisive role in determining the outcome and success of preserving a limb. These include the extent and severity of vascular injury, the bone and soft tissue damage, the type and duration of limb ischemia, the patient's age, the time elapsed from the initial injury to surgery, and concomitant organ injuries. To determine which limbs can be salvaged and which should be amputated primarily, numerous scales using a variety of criteria have been proposed assessing the severity of injury. They include the mangled extremity syndrome, the mangled extremity severity score, and NISSA (N = nerve, I = ischemia, S = soft tissue injury, S = skeletal injury, S = shock, and A = age of patient).

Patients with multiple injuries pose a significant challenge. Optimal management is essential early on after trauma to avoid long-term complications, sepsis, organ failure, and subsequent increased late mortality. The principles of management now include simultaneous assessment and resuscitation, with complete physical examination and diagnostic studies as appropriate to establish priorities for life-saving surgery. Trauma management can be divided into four periods ([Table 1](#)). The primary goal during the acute

Table 1 Periods of trauma management

	<i>Time after trauma</i>
Acute or resuscitation period	1–3 h
Primary or stabilization period	1–72 h
Secondary or regeneration period	3–8 days
Tertiary or rehabilitation period	after 8 days

or resuscitation period is to establish adequate ventilation, maintain circulation (intravascular volume and cardiac function), and assess neurological state. The primary or stabilization period of treatment starts when all vital functions have been stabilized by achieving adequate ventilation, hemodynamic stability, and control of intracranial or internal hemorrhage. During this stage, priorities for surgical treatment after resuscitation are given to brain injuries, eye and facial injuries, progressive compression of the spinal cord, visceral injuries, open fractures, fractures with concomitant injuries to major vessels, pelvic ring fractures, and unstable spine fractures. The secondary period is a phase of regeneration. Reconstructive treatments during this phase include secondary wound closure and soft-tissue reconstruction, osteosynthesis of upper extremity fractures, and complex joint reconstruction. After eight days, in the tertiary period, the prognosis of the polytrauma patient is usually apparent. If recovery continues, final reconstructive operations can be performed, including bone grafting at sites of massive bony defects, special soft-tissue reconstructions, definitive closure of amputation sites, and any remaining procedures that were postponed. In cases with organ dysfunction or respiratory distress (e.g., ARDS), further surgical procedures cannot be considered.

Physiological Responses to Trauma

Early death following multiple traumatic injuries is usually attributed to primary brain injury or significant blood loss (hemorrhagic shock), whereas late traumatic death is usually the result of secondary brain injury and host defense failure. The host defense response system is triggered by a series of insults that occur primarily or secondarily (Table 2). The host defense response is characterized by the local and systemic release of various factors (hormonal mediators, pro-inflammatory cytokines, acute phase proteins, etc.) that make up the systemic inflammatory response.

Adjustments in homeostatic mechanisms occur following trauma in an effort to maintain homeostasis and ensure wound healing. Multiple factors, including

Table 2 Primary and secondary physiological insults

<i>Primary insults</i>	<i>Secondary insults</i>
Hypoxia	Ischemia
Hypotension	Reperfusion injury
Organ and soft tissue injury	Compartment syndrome
Fractures	Operative interventions infections

Table 3 Acute and prolonged responses to traumatic stress

<i>Acute responses</i>	<i>Prolonged responses</i>
Activation of blood-clotting mechanisms	Immunological alterations: mobilization of leukocytes, increased T cells and macrophages, increased acute-phase plasma proteins
Shift of body fluids from extravascular compartment to restore blood volume	Inflammatory cells invade injured area
Blood flow redistributed to ensure perfusion of vital organs	Increased fibroblasts for collagen scaffolds for wound repair
Respiratory and renal functions compensate acid–base balance	

diminished blood volume, tissue underperfusion, extensive tissue damage, and invasive infections initiate the stress-response cascade via the neuroendocrine system. As a result of these initial physiological adjustments, tissue perfusion is maintained, and vital organ function and wound repair are supported.

Major traumatic injury is associated with rapid blood loss, tissue underperfusion, massive cellular damage, and disturbances to vital organ function. Response to the traumatic stress include local changes at the injury site and system changes that occur either acutely or gradually with have a prolonged responses (Table 3).

The events that take place following trauma are generally graded – the more severe the injury, the greater the response. In addition, the responses to trauma change over time and can be divided into acute-phase and chronic-phase changes. The acute-phase changes occur immediately after injury and are characterized by a fall in metabolic functions and a decrease in core temperature and by increased levels of stress response hormones. Many of the changes observed acutely are related to hypovolemia. With the restoration of blood flow and with time, the patient's responses change. In the chronic phase, the metabolic rate rises, body temperature increases, and blood insulin levels reach normal or can be increased (Table 4). The chronic phase following injury is characterized by a hypermetabolic state. The degree of hypermetabolism (increased oxygen production) is generally related to the severity of the injury. Patients

Table 4 Time course in responses to multiple trauma

	<i>Acute phase</i>	<i>Chronic phase</i>
Blood glucose	Elevated	Normal or slightly elevated
Glucose production	Normal	Increased
Free fatty acids	Elevated	Normal
Insulin levels	Low	Normal or elevated
Catecholamines	Elevated	High to normal
Blood lactate	Elevated	Normal
Oxygen consumption	Low	Elevated
Cardiac output	Low	Increased
Core temperature	Low	Elevated

with long-bone fractures exhibit a 15–25% increase in metabolic rate, whereas those with multiple injuries increase metabolic needs by 50%. Patients with severe burn injuries covering over 50% of their body may demonstrate a resting metabolic rate that is twice basal levels.

Multiple trauma injury is a clinical condition that results in a marked activation of neuroendocrine stress response aimed at restoring hemodynamic and metabolic homeostasis. The stress response is activated by diverse physical conditions (e.g., ischemia and glucopenia) and is primarily mediated by the hypothalamic-pituitary-adrenal (HPA) axis and sympathetic systems. The activation of the stress response system appears to be critical for survival from injury.

The Neuroendocrine Stress Response to Trauma

Traumatic injury poses a significant psychological and physiological threat, and it provokes an immediate neuroendocrine response. Neural input from the cerebral cortex, injured tissues, and receptors detecting fluid loss results in increased adrenocorticotrophic hormone (ACTH), growth hormone (GH), prolactin, and arginine vasopressin (AVP) release from the pituitary and in a general activation of the sympathetic nervous system with increases in epinephrine and norepinephrine concentrations. Secondary changes include the stimulation of cortisol and aldosterone. The duration of these responses generally depend on the severity of the injury and varies among hormones. The autonomic nervous system provides a rapidly responding mechanism to control a wide range of functions, including cardiovascular, respiratory, gastrointestinal, renal, endocrine, and other systems.

The stress system consists of three central and two peripheral components. The central components of the stress system comprise the locus ceruleus in the

reticular formation, which regulates arousal; the brain-stem centers of the autonomic system, which regulates sympathetic/adrenomedullary function; and the hypothalamic paraventricular nucleus (PVN), which regulates adrenocortical function. The peripheral components consist of the sympathetic/adrenomedullary system and the pituitary-adrenal axis. The interactions among the various components of the stress system are numerous and complex. Corticotropin releasing hormone (CRH)-secreting neurons of the lateral paraventricular nucleus project toward the arousal and sympathetic system in the hindbrain, and conversely, catecholaminergic fibers from the locus ceruleus and central sympathetic system project via the ascending noradrenergic bundle to the PVN in the hypothalamus. The activation of the CRH neurons in the PVN results in the release of CRH into the hypophyseal portal system and the stimulation of the arousal and sympathetic centers in the brain stem in a positive reverberating feedback loop.

Both endorphins and ACTH secreted by the pro-opiomelanocortin (POMC) neurons of the arcuate nucleus exert inhibitory effects on CRH secretion. As POMC neurons are stimulated by CRH, they provide another negative feedback control loop on the HPA axis. ACTH stimulates the release of cortisol from the adrenal cortex, the latter which feeds back in a negative fashion, both at the level of the pituitary and of the hypothalamus, forming the long feedback loops. The activation of the stress system has direct consequences on the function of other major systems, particularly those responsible for reproduction, growth, and immunity.

Today, the role of AVP in the control of ACTH secretion and its involvement in various stress response paradigms is generally accepted. AVP is released from two sites in the hypothalamus; the parvocellular division of the PVN, where CRH is also formed, and from the magnocellular neurons of the supraoptic nucleus (SON) and the PVN. Recent evidence supports an intricate interaction of AVP with CRH and with glucocorticoids, the inhibitory feedback component of the HPA axis.

It is clear that AVP plays an important role in the stress response. Chronic stress paradigms have shown with relative consistency a shift in the CRH: AVP ratio that may relate to a differing feedback sensitivity of AVP to glucocorticoid feedback restraint or a greater responsivity of AVP, over CRH, to chronic stimulatory stress input. AVP serum concentrations significantly increase in the critically ill patient population. However, the lack of a correlation between AVP concentrations and hemodynamic parameters suggests a complex dysfunction of the vasopressinergic system in critical illness.

Extremely low corticosteroid-binding globulin (CBG) levels in early-stage multitrauma is reflected in a concomitant higher free cortisol index, indicative of higher free cortisol levels. This suggests that CBG plays an active role in the glucocorticoid response to severe stress and the regulation of cortisol availability to target tissues.

Time-Dependent Changes in the Stress Response

It appears that the hypothalamus and anterior pituitary function may be altered differently in the first few hours or days (acute phase) compared to 7–10 days (chronic phase) after disabling multiple traumatic injuries. During the first few hours or days after multiple traumatic insult, circulating GH levels become elevated and the normal GH profile is altered (peak GH levels and interpulse concentrations are high, and the GH pulse frequency is elevated). After a prolonged period, the changes observed with the somatotropic axis change; GH secretion pattern becomes random or chaotic, with a considerable reduction in pulses.

Within a couple of hours after trauma, serum 3,5,3' triiodothyronine (T_3) levels decrease, whereas thyroxine (T_4) and thyroid-stimulating hormone (TSH) levels rise briefly. Later, in the chronic phase, TSH levels are low to normal, and T_3 and T_4 concentrations are low. Prolactin levels show a pronounced increase following trauma. In the chronic phase, on the other hand, prolactin secretion is blunted. It has been suggested that this may play a role in the anergic immune dysfunction and in the increased susceptibility to infection observed at this time.

The stress-induced hypercortisolism triggered by trauma is associated with elevated ACTH release, which, in turn, is augmented by CRH, cytokines, and the noradrenergic system. Circulating aldosterone also rises markedly, and this may be attributed, at least in part, to the activated renin-angiotensin system. Hypercortisolism acutely shifts carbohydrate, fat, and protein metabolism, so that energy becomes available to the vital organs, such as the brain, and so that anabolism can be delayed. Intravascular fluid retention and enhanced AVP response provide hemodynamic advantages for the fight-or-flight stress response. Finally, the hypercortisolism induced by acute trauma may reflect an attempt by the organism to dampen its own inflammatory response. There is some evidence of a biphasic time course with the eventual dissociation of ACTH and cortisol concentrations following major trauma or surgery. Although there is some evidence of a possible role of endothelin

and/or atrial natriuretic peptide (ANP) in this dissociation of concentrations of cortisol and ACTH, the mechanism or significance of this in the regulation of HPA axis function in the critically ill or stressed is not clear.

In the chronic phase, serum ACTH levels drop and are low, whereas cortisol levels remain high. This suggests that cortisol release in this later stage may be driven by a different pathway. On the other hand, circulating levels of adrenal androgens (dehydroepiandrosterone sulfate, DHEAS), which has an immunostimulatory effect on T helper (Th)-1 cells are low during the chronic state. Some suggest that sustained hypercortisolism in the presence of low levels of DHEAS and prolactin in the chronic phase could provoke an imbalance between immunosuppressive and immunostimulatory pathways, which could increase susceptibility to infections.

Taken together, the neuroendocrine stress response differs in the acute and chronic phases following traumatic injury. Initially following trauma, the anterior pituitary actively releases hormones into the circulation, whereas anabolic target organ hormones are inactivated in the periphery. In the chronic state, the pulsatile release of anterior pituitary hormones becomes reduced, presumably because of reduced hypothalamic stimulation. The end result is diminished activity of target tissues and impaired anabolism.

Immune System Response to Trauma

The increased stress response after traumatic injury is associated with altered immune function and decreased immunity. The immune function of most patients is suppressed as a result of their traumatic injuries. Immunological changes after multiple trauma correlate with the degree of tissue damage, as well as with severity of hemorrhage and ischemia. Trauma has been found to significantly depress polymorphonuclear and monocyte functions, with both the phagocytic and bactericidal functions of these cell types being depressed. For the most part, immune changes are attributed to excessive cortisol levels.

Corticosteroids represent one of the most potent endogenous anti-inflammatory agents known. They have the capacity to inhibit and suppress virtually all critical inflammatory and immune cell functions, even at physiological concentrations and particularly during the early development of the immune/inflammatory response. At the molecular level, they inhibit the production of most inflammatory mediators, including interleukin (IL)-1, tumor necrosis factor (TNF), phospholipase A₂, and prostaglandins. Hence, the stress-induced enhanced production and secretion of glucocorticoids appears to counterregulate and

suppress excessive immune/inflammatory cell activation and mediator production that could otherwise result in self-induced tissue injury. This suggests a critical role for the corticosteroids in maintaining physiological homeostasis during the adaptive response to noxious stressors.

Several neurohormonal systems and immunological factors appear to play a fundamental role in these communicatory links, which enable the peripheral immunological apparatus to signal and interact with the brain and participate in maintaining immunological homeostasis. This is facilitated by an extensive coexpression of receptors and overlap of the synthesis of a multitude of hormonelike molecules that regulate cell function. In this regard, IL-1, a major product of activated macrophages, has been extensively studied. IL-1 receptors are expressed not only on peripheral T lymphocytes but also in the brain, where, in addition, it is synthesized. In addition to regulating a wide range of neural functions, including arousal, body temperature, sleep, food intake, reproductive behavior, and mood, that appear to be under direct central nervous system (CNS) control, some of the actions of IL-1 on peripheral immune function also appear to be mediated by IL-1 in the CNS. However, the relation of CNS IL-1 to peripheral immune system-derived IL-1 remains to be elucidated. IL-1 is also a potent stimulator of the HPA axis, resulting in the release of corticosteroids. Corticosteroids, in turn, feed back to inhibit macrophage release of IL-1. Other examples of this intricate communication between the immune and nervous system are rapidly being characterized.

Recent evidence suggests that there are two major pathways by which the CNS can regulate the immune system. The first pathway is through neurohormonal systems, particularly the HPA, or stress, axis. Other neurohormonal systems that appear to also play important roles include the hypothalamic-pituitary-gonadal (HPG) axis, the hypothalamic-pituitary-thyroid (HPT) axis, and the hypothalamic-growth hormone axis. The second major pathway is the autonomic nervous system and the release of norepinephrine and acetylcholine. Glucocorticoids inhibit the functions of virtually all inflammatory cells via the alteration of transcription of cytokine genes (TNF, IL-1, and IL-6) and inhibition of the production of arachidonic acid-derived pro-inflammatory substances, such as leukotrienes and prostaglandins.

Conversely, the immune system modulates CNS function through various factors, particularly cytokines, which can act independently or synergistically. The CNS contains IL-1 receptors in areas that control the acute-phase response. In addition, IL-1 stimulates

the production of endothelial cell prostaglandins, which in turn, induce CRH release from the median eminence. In contrast, IL-6 acts as a potent stimulator of ACTH and cortisol release. In healthy individuals, this bidirectional regulatory system forms a negative feedback loop, which keeps the CNS and immune system in balance.

The efferent sympathetic/adrenomedullary system apparently participates in an important way in the interactions of the adrenal axis and the immune/inflammatory reaction by being reciprocally connected with the CRH system, by receiving and transmitting humoral and nervous immune signals from the periphery, by innervating lymphoid organs, and by reaching all sites of inflammation via the postganglionic sympathetic nerve fibers.

Posttraumatic Psychological Complications

Multiple trauma injury poses a significant challenge to patients' perception of control over their environment. The various and multiple stressors presented not only by the traumatic episode itself but from the sequelae of events following the accident (multiple surgeries, diagnostic tests, etc.) diminish patients' perception of control, resulting in additional, although subjective, activation of the stress response.

Psychological complications are an important and persistent factor after injury and are associated with adverse effects on the daily activities of the patient. Multiple-trauma patients have been reported to suffer from loss of initiative, irritability, mood swings, feelings of guilt, among others, assessed using the State/Trait Anxiety Scale. The prevalence of posttraumatic stress disorder (PTSD) and symptoms of depression and anxiety in severely injured polytrauma patients is not clear. It appears, however, that the incidence of PTSD is low following multiple traumatic injuries in victims who were healthy before experiencing the trauma. Nonetheless, a substantial proportion of severely injured accident victims develop some form of psychiatric morbidity.

During the first few hours and days following a serious multitraumatic injury, most patients have at least short periods of anxiety with dissociative symptoms, such as derealization, occurring for a short duration in approximately 15% of the patients. Over the following weeks and months, the rates of PTSD reported range from 8 to 39%. A few long-term follow-up studies (28 months) report psychiatric morbidity, mostly depressive disorders, in approximately 22% of trauma victims and PTSD in 8% after 5 years.

The physical causes of biomechanical strain induced by frequent or enduring postural work demands.

Passivity due to fear of the pain expected from movements.

Pain from the skeletal muscles.

Pain from the fasciae that cover the skeletal muscles.

Skeletal muscles named after their microscopically observable striated pattern of muscle fiber arrangements. These fibers are of two major kinds: one is designed for aerobic metabolism and the other for anaerobic metabolism (in which oxygen is not involved). Individuals differ in their proportion of fiber types, mainly due to genetic disposition.

Pain from the tendons of the skeletal muscles.

Skeletal muscles represent the only case in which the brain can exert some degree of volitional control over the activity level of an organ. Despite this fact, much pain, stiffness, and discomfort are presented to the health-care system as originating in the skeletal muscles. It is perceived by the patient as beyond control.

Epidemiology of Musculoskeletal Pain

Most musculoskeletal problems present as nonspecific pain, that is, pain that has no obvious and verifiable cause. Often it is due to a complex constellation of ergonomic, physiological, motivational, and emotional load factors that act on biological mechanisms involved in pain perception. Not all pain is attributable to a particular body area. A major diagnostic criterion in fibromyalgia is the presence of widespread pain. However, the most prevalent types of muscle pain involve the neck, shoulders, and lower back; the extremities may also be involved (mostly the gastrocnemius muscle of the legs and the flexor muscles of the forearms).

A major proportion of muscle pain is due to myalgia, myofascial pain, and pain from the tendons of muscles, referred to as tendonitis. In the lower back, the muscles involved are the *musculus (m.) erector spinae*, *m. iliocostalis lumborum*, and *m. gluteus medius*. In the neck and shoulders, the *m. trapezius*, *m. deltoideus*, and muscles covered by these superficial muscles are also prevalent sources of pain.

Muscle pain is not always taken to the health-care system. In most cases, the pain and related discomfort is mild and involves transient disability or the pain is treated by the consumption of over-the-counter analgesics. It has been estimated that, on average, 30–40% of musculoskeletal pain relates to work and that severe episodes of low back pain may occur in less than 5% of the population. However, the 1-year prevalence of musculoskeletal pain may be as high as 50% among adults in Western societies. In a recent study involving 70% of a county population ages 20 and above ($N = 64,690$), the 1-year prevalence, including less severe episodes of muscle pain, was as high as 50.1% in females and 42.6% in males. Continuous pain and discomfort for at least 3 months were most prevalent in the neck, shoulders, and lower back (females: neck = 19.4%, shoulders = 21.1%, lower back = 17.4%; males: neck = 14.5%, shoulders = 16.8%, lower back = 14.2%). In preadolescents, persistent pain may be as prevalent as 15%, with pain in the neck and lower extremities accounting for a major proportion of this pain, particularly among the girls.

There was a shift toward multidisciplinary paradigms in musculoskeletal pain research after 1985 with the increasing acknowledgment of psychological and psychosocial factors. On the behavioral side, more children and adults are physically inactive in everyday life than ever before, although mental activity may be high in front of a visual display unit or television screen. On the other end of this skewed distribution of physical activity level is a small

percentage of the adolescent and young adult population that is extremely active in competitive sports. Both lifestyles increase the risk of musculoskeletal pain but for different reasons. Inactivity causes the atrophy of skeletal muscle and poor circulation, resulting in poor workload tolerance; sport injuries cause pain due to physical overload, mishaps, and accidents.

Muscle Fiber Contraction, Hardness, and Pain

Human muscles are of three kinds. They are distinguished mainly by the anatomical microstructure that can be microscopically observed by histological inspection. (1) Striate (skeletal) muscles have a striated pattern, reflecting the special arrangement of muscle fibers side by side; they contract on stimulation by nerves in the pyramidal and extra-pyramidal systems. (2) Smooth muscles induce movements in internal organs, including the digestive tract and blood vessels; they lack a striated pattern and contract on stimulation by the autonomic nervous system. (3) The heart muscle has a semi-structured arrangement of fibers and is stimulated by nerves in a special section of the autonomic nervous system. A number of other factors modulate the neural stimulation of muscles, including neurotransmitters, hormones, and the acid–base balance of the body.

Muscles can also be classified according to the dimensionality of their movements. Skeletal muscles induce one-dimensional movements due to the attachment of their tendons to the skeleton across joints. In contrast, smooth muscles induce two-dimensional movements by the compression of the diameter of a tube (e.g., blood vessel); the heart muscle fiber contractions induce three-dimensional movements to reduce the globular volume and act as a pump.

Skeletal muscles harden with contraction. Activation from complete relaxation to maximum voluntary contraction (MVC) presents a substantial change in muscle hardness that is easily palpable, whereas a shift from relaxation to 5% of MVC can be accurately assessed only by the use of modern pressure technology and electromyography (EMG). In EMG, surface and implanted electrodes pick up neuroelectrical impulses generated by motor nerve activation. Research has supported a relationship between hardness and tenderness in the trapezius muscle of patients with chronic tension-type headache. This relationship is present also on days without pain and, therefore, indicates a permanent alteration of muscle hardness and tenderness that is different from that of healthy controls. Also, the mechanism is more enduring and

extensive than those responsible for the perception of pain from these muscles.

Skeletal muscles are composed of a mixture of aerobic and anaerobic fibers (see [Figure 1](#)). There are remarkable individual differences in the ratio of aerobic (type 1) to anaerobic (type 2) fibers among individuals. These differences are genetically given. A subset of the type 2 fibers, the type 2A fibers, can perform aerobic metabolism when forced to do so, whereas the type 2 B fibers are nearly always anaerobic. Oxygen is needed in aerobic metabolism, and carbon dioxide is a waste product. Oxygen is not involved in anaerobic metabolism, and lactic acid is a waste product that can be used by type 1 fibers for aerobic metabolism. This is to say that the blood circulation brings oxygen to the aerobic fibers and washes out harmful carbon dioxide from the local tissue, whereas the waste product from type 2 fibers, lactic acid, can be exploited by neighboring aerobic fibers and, therefore, puts less demand on the systemic circulation. Aerobic fitness training makes aerobic fibers more efficient at aerobic metabolism, but it does not increase the number of genetically given aerobic fibers. Elite marathon runners may have 80% of aerobic fibers in their leg muscles, whereas elite sprint runners have around 80% of anaerobic fibers in their leg muscles.

The genetic differences are often forgotten when people explain why they intuitively feel they are not made for aerobic activities such as long-distance running, cross-country skiing, and other endurance activities at a moderate intensity. Conversely, they also shed light on why others display an intuitive distaste for anaerobic activities such as sprinting and downhill skiing. Most individuals have a good balance between type 1 and 2 muscle fibers and, therefore, are capable of performing aerobic as well as

anaerobic work to a reasonable degree. Some individuals are strongly genetically biased toward a high tolerance for anaerobic work only, whereas others have a remarkable tolerance for aerobic work production without experiencing muscle pain.

Sperry's Principle: Brain Control of Muscle Tension

The sole product of brain function, including our thinking mechanism and the related mental functions of motivation, emotion, attention, and memory, is muscular coordination. Skeletal muscles make up most of the body mass in humans. Consequently, perceptual-motor control of the skeletal muscles presents the most extensive challenge to the brain's capacity for information processing. The perceptual component in motor control is a less extensive challenge than is the challenge of motor coordination. This perspective on the brain's control of body functions is named Sperry's principle.

The musculoskeletal system is the biological substrate for volitional behavior in the common sense. The dynamics of motor activity is also the basis for displays of expressive behavior, despite the often unintended nature of such displays, and other elements of body language including body posture. The way we sit on a chair and stand by the desk involves a much more automatic coordination of complex muscle tension patterns than is involved in the volitional movement of a finger to release a button. Walking toward a good friend involves the activation of a whole range of muscle coordination, including automated control of walking, the expression of a friendly display as well as raising a hand to say hello. The ballistic smoothness of such movements in space is taken care of by integrated input from the cerebellum.

Figure 1 Major differences in metabolic energy production between aerobic (type 1) and anaerobic (type 2) muscle fibers. Note that lactic acid is a waste product from type 2 fibers and can be available for subsequent aerobic metabolism in type 1 fibers. ATP, adenosine triphosphate (the work horse in muscle contractions).

The Pyramidal Pathway of Muscle Control

The most remarkable connection between the cortex of the brain and the skeletal muscles is called the pyramidal tract. Nerve fibers in this tract originate in the motor cortex and synapse with a second nerve fiber in the spinal tract to make the nerve impulse from the cortex initiate contraction in a group of skeletal muscle fibers. There is no other example of a monosynaptic connection from the cortex of the brain to a target organ in the body. This arrangement is responsible for the precise control of intended movements with minimal interference from other parts of the brain. The brilliance of this volitional control can become remarkable with practice, as professional musicians, and in elite athletes.

A motor nerve fiber from the brain to the muscle terminates by splitting up into several endings to stimulate simultaneously a group of muscle fibers in a single motor unit (SMU). All fibers in one SMU are of the same kind (type 1 or 2). The number of fibers may vary between approximately 10 and 200, with small SMUs in muscles involved in precise motor control, such as in the muscles of the fingers, and with large SMUs involved in the postural muscles of the trunk.

The Extra-Pyramidal Pathways to the Skeletal Muscles

Body posture is regulated via the extra-pyramidal pathways from the brain to the skeletal muscles. These influences originate subcortically and, therefore, are subject to automated induction of tension patterns. Several such pathways are integrated as parts of the basal ganglia between the thalamus and the cortex. One extra-pyramidal pathway originates in the reticular formation of the medulla oblongata and is a powerful modulator of skeletal muscle tension levels throughout the body. This pathway provokes muscle tension with increasing anxiety, alertness, and levels of effort to assure a stabilizing platform for intended actions as part of the attentional demands and flight-or-fight adaptive mechanisms of the hypothalamus and limbic system.

All extra-pyramidal pathways to the skeletal muscles are multisynaptic and can receive input from several other subcortical connections. This fact explains the chronic nature of many tension-related muscle problems and why they are influenced by a number of psychological processes that are beyond volitional control. It also explains the frequent need for an adjustment of lifestyle, including physical exercise habits and interpersonal competence, in the rehabilitation of musculoskeletal-pain patients, as well as why it is a time-consuming challenge to recover from musculoskeletal-pain problems.

Motivation, Emotion, Muscle Tension, and Performance

Brain activation of muscle tension is often due to task involvement, which is influenced strongly by motivational processes. Long ago, Malmö demonstrated that the intensity of motivational involvement in perceptual-motor tasks provokes increasingly higher tension levels in muscles that are not strictly involved in the demands that are extrinsically given by the nature of the task. One example is the operation of a joystick by the dominant forearm; muscle tension gradients build up in the nondominant forearm, which is never called on by the extrinsic nature of that task. He demonstrated that such generalized gradients of muscle tension tend to become more marked with increasing interest, anxiety, and effort. The quality of the performance may also improve with the increasing gradients of tension.

Quality versus Intensity of Motivational States

Apter and Svebak reviewed a series of EMG experiments on muscle tension patterns provoked by the performance of a perceptual-motor task in a playful versus serious-minded motivational state. They concluded from these experiments that playful task involvement with high effort provokes a pattern biased toward high pyramidal activation of muscles called on by the extrinsic nature of the task and low extra-pyramidal tension gradients in background muscles. Serious-minded task involvement consistently provoked gradients of high tension buildup in the seemingly passive muscles of the nondominant forearm, the legs, and the neck when the dominant forearm was actively performing a perceptual-motor task. These states of motivational involvement can be manipulated with some success by the use of extrinsic incentives such as the promise of a monetary bonus for a good performance or the threat of aversive electric shock for a poor performance. Incentives improve performance, whereas the qualitative distinction between serious-mindedness and playfulness has been reflected less clearly in the quality of perceptual-motor performance.

Playfulness and serious-mindedness are facets of personality. Some individuals are dominated more of the time by one of these motivational states, whereas others reside in the opposite state. When extrinsic incentives are not manipulated, motivational dominance explains why some people present with enduring and seemingly unprovoked muscle tension patterns that are not present in others performing the same type of perceptual-motor task. When extrinsic incentives are manipulated, they may interact with aspects of personality, which explains some of the, often paradoxical, differences of workload tolerance across

individuals. The incentive that is perceived as a threat by one person may be welcomed as an exciting challenge by another.

Personality and Sensitivity to Emotional versus Ergonomic Loads

Patients with chronic low back pain (i.e., daily pain for more than 3 months) have elevated scores on somatization disorder without meeting the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) criteria for this diagnosis. Some of these pain patients also tend to report the incidence of lifetime major depression as well as alcohol dependence. Other personality factors can increase the risk of back pain when challenged by the nature of the workload. One example is a high emotional load. Hospital staff members in some wards are exposed to high emotional loads when working with chronically ill children and their parents or when employed as a midwife, situations in which a life-threatening crisis can present without much warning. Employees who score high on neuroticism, with a tendency to overrespond with anxiety, worry, and other dysphoric moods when faced with emotional stressors, are at increased risk of suffering from pain in the neck and shoulders. In contrast, staff members in wards with a predominantly high ergonomic load are at increased risk of low back pain. This risk is mediated, provided they score high on personality traits reflected in habitual impatience and the willingness to respond on impulse with a high motor effort when coping with such a load.

Personality can increase the risk of musculoskeletal pain in ways that distinguish ergonomic from emotional load factors. They can also add to local tissue damage and cause muscle pain as a result of nested vicious circles of algogenic processes (see [Figure 2](#)). With ergonomic load, the brain activates muscles predominantly via the pyramidal pathways to induce intentional movements. The speed and force components can induce muscle and tendon ruptures as well as pain from a high spinal load on disks, which respond with hernias that may irritate local nerves and give rise to irradiating pain. An increased risk of such ruptures occurs when high force is provoked by an impulsive brain discharge into the striate muscles with a composition of fibers designed for low enduring loads (type 1 fibers). Ruptures of tendons can be provoked, and pain from inflammatory processes may be provoked as secondary consequences of these ruptures also involving the fasciae of muscles.

With emotional load, the extra-pyramidal pathways from the brain to the muscles become more

Figure 2 Relationship among factors in musculoskeletal load, their time and intensity parameters and their tissue tolerance. Arrows indicate hypothesized patterns of nested vicious circles in musculoskeletal pain.

activated and induce enduring tension in muscles not strictly called on by the extrinsic nature of motor tasks. These activation patterns are likely to have side-effects on blood circulation through the muscles, resulting in local ischemia. The brain activation pattern may also be in conflict with the local tolerance for enduring a low workload due to a bias toward anaerobic type 2 muscle fibers, which are quickly exhausted. The resulting tissue damage provokes inflammation that gives rise to pain.

Central Nervous System Mechanisms of Pain Sensitivity

Several brain processes can significantly influence pain sensitivity. The perception of pain is always subjective. Pain can be perceived with no biologically definable cause. In contrast, large tissue damage may not always give rise to the perception of severe pain. Also, pain thresholds tend to fluctuate throughout the day and over weeks. One reason for these poor relationships between the degree of tissue damage and pain perception is purely due to a shift in the focus of attention. Pain is mediated in unemployment

where body awareness can be facilitated in the lack of extrinsic attentional demands. Hypnotic and meditative techniques guide a shift in the focus of attention away from pain and may also induce relaxation.

Brain Neurotransmitters

Several neural pathways and chemical neurotransmitters of the brain modulate sensitivity to pain. Until recently, most brain research on pain sensitivity concentrated on the thalamus; now it has become evident that many areas of the brain modulate pain perception. The spinothalamic tract is the most predominant nociceptive pathway for this cortical input, but the spinoreticular pathway is also acknowledged to be important, and they both terminate in the somatosensory cortex where there are small receptive areas that explain the perception of pain in discrete areas of the body but not the diffuse nature of most clinical pain. A third pathway is the spinomesencephalic pathway that terminates in the periaqueductal gray matter of the midbrain, an area rich in opioid receptors. All these pathways modulate pain perception.

The main neurotransmitters in the cortex are glutamate (pyramidal cells that are excitatory) and γ -aminobutyric acid (GABA; nonpyramidal cells that are inhibitory). Anxiolytic medication acts on GABA to facilitate neuroelectric inhibition. The cortical degeneration of glutamate receptors is a monotonous process from birth to the onset of puberty. Early onset means there will be a higher density of glutamate receptors than late onset. Subcortical serotonergic neurons inhibit pain perception. Serotonergic hyposecretion tends to provoke dysphoric moods such as irritability and depression. Endorphins act like morphine and moderate pain sensitivity (via the opioid receptors). Their secretion is believed to increase with good moods and to decrease with bad moods. However, personality factors may play a more important role than moods in the psychological regulation of the endorphins, and personality as well as mood states may influence other pain-modulating transmitters more than they influence endorphin secretion. Enkephalins are also endogenous opioids and decrease pain sensitivity.

In 1992, the endogenous cannabinoid (cannabis-like molecules) brain system was discovered and, since then, has attracted much research due to its ubiquitous receptor in the brain. These molecules bind to the CB₁ receptor that is densely distributed in areas related to motor control, emotional control, cognition and motivated behavior. These new insights may provide cannabinoid receptor antagonists and improve clinical approaches to a diversity of problems including pain, obesity, anxiety and drug addiction.

Spinal and Peripheral Mechanisms

The gate control theory of pain sensitivity was proposed by Melzack and Wall in 1965 to include free nerve endings in the deeper layers of the skin. These nerve endings respond to touch by inhibiting the spinal transmission of pain signals from the body to the brain. The pleasant component of being touched can also induce a shift in mental state that, subsequently, induces increased pain thresholds via changes in pain neurotransmitters of the brain. A therapeutic circle of events is indicated by the fact that the spinal pain-transmission peptide, substance P, is regulated via the secretion of serotonin in the brain. All mental influences that raise the secretion of brain serotonin also increase the concentration of substance P in the brain, which, again, increases spinal serotonin, which, in turn, reduces spinal substance P and therefore reduces pain sensitivity.

Coping with Musculoskeletal Problems: Prevention and Rehabilitation

There is probably no better way to prevent nonmalignant musculoskeletal pain and discomfort than to develop sensory-motor competence from early childhood and to maintain this competence throughout life. And yet there is no guarantee. A healthy ego development is based on the acquisition of sensory-motor skills. Through play, work, and sports, experience gradually builds to provide a solid basis for the individual to define those motor activities that are intrinsically felt to be right. There is no better way to find out what one's own skeletal muscles are good at and where their tolerance limits are. It is more important to health for an individual to maintain a level of physical fitness that is felt to be intrinsically rewarding than to meet some socially mandated standard prescription such as jogging three times a week for at least 20 min. Not all individuals are genetically equipped with skeletal muscles made for aerobic exercise, but all are made to be active.

Work-related musculoskeletal pain and discomfort often reflect a mixture of biomechanical (postural), physical (climatic factors and lightening noise), and psychosocial (mental demands and psychosocial relationships) exposures. An extensive review of ergonomic intervention studies by Westgaard and Winkel concluded that successful outcomes are due to (1) organizational culture interventions with high commitment of the stakeholders, (2) the use of multiple interventions to reduce identified risk factors, and (3) the modification of risk factors for the individual workers at risk, using measures that ensure the active involvement and support of the worker.

Figure 3 The dynamic relationship among important elements in rehabilitation of musculoskeletal pain. Arrows indicate hypothesized patterns of nested self-rewarding benign circles in the psychobiological development of musculoskeletal competence.

Multidisciplinary intervention programs have been recommended for nonmalignant musculoskeletal pain since the 1970s. A review of 65 treatment outcome studies for back pain was published in 1992. These studies included a diversity of treatments across the psychological, medical, physical, and occupational fields. They lasted, on average, 7 weeks with a range of from 1 to 31 weeks. Hours spent in treatment ranged from 4 to 264, with an average of 96 h. The site of pain in most studies was reported to be the back or in heterogeneous locations. The results from a meta-analysis clearly support the conclusion that multidisciplinary treatments for nonmalignant chronic musculoskeletal pain are superior to single-discipline treatment, waiting list, and no treatment. And the effects have proven to be stable over time. Interestingly, the effects also extend beyond the reduction of pain. Patients report improved mood, a high frequency of return to work, and a reduced need for support from the health-care system after multidisciplinary treatments (Figure 3). These early findings are strongly supported in recent research.

Patients must be encouraged to be physically active; the recommendation of a passive lifestyle is not a professional treatment. In this encouragement, fear avoidance may be the major obstacle. This concept was introduced in 1983 by Lethem et al. to account for a passive lifestyle in patients with chronic musculoskeletal pain, in which the avoidance of movements that are expected to give rise to pain leads to the maintenance or exacerbation of fear. The effectiveness of rehabilitation is improved when the patient learns to orient him- or herself away from patterns of passive avoidance and toward active confrontation with pain and the related fear. Multidisciplinary

treatments of groups of outpatients with various diagnoses, of various ages, and of both genders are best at overcoming pain-related fear. And professionals, beyond being academically skilled, also should be socially competent to provide emotional security as well as facilitate motivation and fun.

Conclusion

Glossary

<i>Electro-diagnosis</i>	A method of evoking electrical responses or recording spontaneous electric responses from nerves and muscles, as well as from the neuromuscular junction, in order to localize pathology to one or more of these specific regions.
<i>Fatigue</i>	A diminishing in muscle strength that is measurable but often without clear anatomic or organic explanation.
<i>Muscular dystrophy</i>	A progressive, untreatable muscle disease defined by scarring and inflammation on histology. The condition is generally recognized as inherited.
<i>Myalgia</i>	Pain attributed to a muscular origin.
<i>Myositis</i>	The inflammation of muscle creating pain, fatigue, and weakness. It is generally proximally predominant.

Myopathy defines a category of neurological diseases affecting muscle proteins and muscle cell substructure, muscle membrane, and other subcellular chemical constituents involved in the transduction of carbon-bond energy into muscle contraction.

Muscle Structure

Skeletal muscle contracts voluntarily, requiring the transduction of a nerve action potential to a chemical message at the neuromuscular junction. This elicits an end-plate potential in the muscle membrane, bringing the membrane to its electrical threshold, which results in calcium release throughout the muscle cell, initiating conformational changes in subcellular proteins (actin, myosin, and troponin) and shortening of the muscle cell, generating force.

Muscle tissue histochemically is a mosaic of muscle proteins surrounded by a muscle membrane, called endomysium, and grouped into fascicles by perimysial connective tissue. The entire muscle is enclosed by a connective tissue cocoon continuous with the perimysium, known as the epimysium, which in turn is continuous with tendon tissue. This bonding of the entire muscle substructure across joints directs the vector of contractile force of each muscle cell in a similar direction, resulting in a coordinated contraction of muscle and flexion or extension of a limb.

Muscle histologically appears as a mosaic due to the dark or light staining characteristics of subcellular proteins involved in fast or slow muscle contraction. Whereas some muscles are dominated by one type and twitch quickly, others are dominated by slower contracting cells, conserving energy. The adaptive advantage of fast- or slow-twitch muscle fibers has a teleological explanation in the response of the organism to threats in the environment. Muscles that have a predominance of fast-twitch fibers are the limb and eye muscles, allowing the organism to respond quickly either toward prey or away from predators, determining whether the organism survives by getting nourishment or avoiding danger. These muscle cells twitch with a great force, but they cannot sustain that force for long. Slow-twitch fibers can contract with reasonable force indefinitely, as long as the pathways for the energy breakdown of fatty acids exist. Such muscles are involved in sustained activity and not necessarily in fight, fright, or flight activity.

Electrical impulses generate neurotransmitter release into the neuromuscular junction, resulting in electrical responses at the muscle membrane, which are carried to all parts of the muscle cell through a complicated system of invaginations of the muscle membrane known as the T tubule system and sarcoplasmic reticulum. These electrical responses are then transduced into the release of calcium from the sarcoplasmic reticulum into the cytoplasm of the muscle cell, known as the sarcoplasm. The interaction of calcium ions with filaments of the muscle proteins actin and myosin allow these strands, lying parallel, to be drawn against one another longitudinally along the muscle cell axis to shorten it. This is an ATP-dependent process. Damage to signal transduction along this pathway results in weakness that may be abrupt and permanent, fluctuating, or relentlessly progressive, depending on the pathophysiology and location of the damage.

Fatigue can result from the functional breakdown at any one of these levels, even at the mental or central nervous system level. Fatigue implies that normal forces are being initially generated and cannot be maintained. It can be measured more easily than its cause can be specifically elicited. Stress to any part of the nerve, neuromuscular junction, and muscle, as well as muscle subcellular structure, can exceed the capacity of the system elements to work synergistically, resulting in diminished muscle strength, which is perceived as fatigue by the individual.

Diseases of Muscle

The variety of muscle diseases reflects the specific localization of pathology in the muscle substructure. Scores of separate muscular dystrophies, inflammatory, and metabolic conditions have been described.

Muscular Dystrophies

Dystrophinopathies Dystrophinopathies are defined by abnormalities of the large structural protein dystrophin, which was first described in the late 1980s, revolutionizing the study of Duchenne muscular dystrophy. Abnormalities of the structural protein depend on genetic problems in the gene for dystrophin at Xp21. Duchenne and Becker muscular dystrophies fall into this category.

Duchenne muscular dystrophy, the most common muscular dystrophy in children, is inherited in an X-linked recessive manner. Females carry the gene, and their male offspring have a 50% chance of manifesting the disease, depending on whether they inherit the abnormal X chromosome. Although the symptoms generally do not appear until early childhood, serum muscle enzymes are frequently elevated

in infancy. The upper extremities are usually affected later than the lower ones in a proximal to distal fashion. Walking is generally not possible by puberty. During late adolescence, the respiratory muscles are significantly compromised and the cardiac muscle is affected. These two manifestations, as well as the general danger of immobility, resulting in deep vein thrombosis, pneumonia, and skin breakdown, are the general causes of mortality. Dystrophin is absent from muscle tissue.

Becker muscular dystrophy differs from Duchenne muscular dystrophy in that the age of onset is later, the rate of progression slower, and the disease is not terminal. Abnormal dystrophin occurs in muscle. Becker muscular dystrophy refers to numerous abnormal dystrophy subtypes. The lethal disturbance in the dystrophin gene, resulting in the low or abnormal translation of effective dystrophin, is unique for each subtype. The muscle substructure is then prone to inflammation, scarring, and the general pathological characteristics necessary for histological diagnosis.

Myotonic muscular dystrophy This is the most common muscular dystrophy in adults. The pathophysiology is unclear; however, the genetics of this very commonly underdiagnosed condition is different from the dystrophinopathies. Myotonic dystrophy is inherited in an autosomal dominant pattern. It is a multisystem disease that includes cardiomyopathy, cataracts, endocrine problems, and central neurogenic hypoventilation. The prevalence is 1 in 20,000. Variations in the phenotype of the disease occur despite the classical description of individuals with this syndrome as having neck flexor atrophy along with ptosis; some patients have a normal physiognomy. Some patients endure muscle cramps, whereas others have a disease incompatible with a normal life span due to cardiopulmonary problems. All suffer cataracts by age 40. It is very slowly progressive in most patients.

By definition, myotonia is a problem of impaired muscle relaxation secondary to the depolarization of the muscle membrane and impaired repolarization. Characteristic electrodiagnostic findings are waxing and waning repetitive motor-unit action potentials with the characteristic audible sound of a dive bomber. This electrodiagnostic finding is not specific for myotonic muscular dystrophy but is present in all the myotonic diseases, suggesting that the disease itself is a muscle membrane disorder. In the early 1990s, the gene for myotonic dystrophy was mapped to chromosome 19, but the gene product has not been identified clearly. The likely candidate is a protein kinase involved in the function of numerous tissues within the body, thus explaining the pleiotropism of

the disorder. Myotonic muscular dystrophy is one of the trinucleotide repeat sequence diseases. The repetitive appearance of three nucleotides in sequence may occur up to thousands of times within the gene, resulting in genomic instability.

Congenital forms This designation includes obscure, slightly progressive, or nonprogressive diseases clearly present at birth. Patients may manifest mental retardation, seizures, and anatomical brain abnormalities. Muscle pathology is variable, including rodlike structures and central cores. Heritability is varied.

Inflammatory Myopathies

Polymyositis Polymyositis is an inflammatory T-cell-mediated dysfunction of muscle cells, with high serum creatine phosphokinase (CPK), white cell invasion of muscle cells, and progressive proximal weakness. It responds well to steroids.

Dermatomyositis Dermatomyositis is a B-cell-mediated disease of muscle and muscle vasculature, also affecting the skin. It is associated controversially with underlying malignancy.

Inclusion body myositis Patients with clinical manifestations of polymyositis who do not respond to prednisone probably have inclusion body myositis (IBM). With more advanced pathological examinations, many victims of steroid unresponsive polymyositis have been found to have vacuolated muscle fibers, mononuclear cell invasion, and amyloid deposits and tubular filaments by electron microscopy. The discovery of amyloid in muscle fibers, along with inflammation, prompted a trial of immunosuppression to determine whether the suppression of the inflammatory response would result in improved strength; this did not occur. The amyloid degeneration in victims of this disease may be similar to the amyloid degeneration seen in the brains of patients with Alzheimer-type dementia. Therefore, IBM may indeed be a primary degenerative disease, such as amyotrophic lateral sclerosis or Alzheimer-type senile dementia. If the theory is correct, this does not bode well for immunomodulating therapeutic trials.

Metabolic Myopathies

Metabolic myopathies are separated predominantly into glycogen-storage diseases and mitochondrial disorders; these genetically determined abnormalities of glucose and fatty acid metabolism result in myoglobinuria, severe muscle weakness, and disordered acid-base homeostasis. They are a cause of occult fatigue in numerous patients and can be difficult to

diagnose. The fact that the mitochondrion possesses its own genome complicates heritability further and underscores the relationship between cytoplasmic inheritance and nuclear inheritance in many of these disease states.

Glycolytic pathway pathology Abnormal metabolism of the stored form of glucose (glycogen) is determined by numerous heritable defects in glycolytic and glycogenolytic enzyme pathways. The lack of phosphofructokinase, phosphoglycerate kinase, lactate dehydrogenase, and phosphoglycerate mutase results in myoglobinuria with exercise. In these conditions, glucose cannot be used efficiently as fuel for muscular contraction, and cramps and myalgia occur with exertion. When the exertion is significant, muscle breakdown occurs and serious systemic consequences can result, such as acidosis and renal failure. An outmoded method of diagnosing glycogen-storage diseases involved exercising a muscle under ischemic conditions and failing to record an appropriate rise in venous lactate; the sophisticated enzymatic analysis of muscle biopsy specimens has supplanted this test. Exercise intolerance is generally the rule in these disorders, and hypoglycemia can occur as well. Therapy is largely related to altering the patient's level of activity and ratio of protein to complex carbohydrate intake.

Mitochondrial myopathies Mastery of the evolving field of mitochondrial myopathies is complicated by almost monthly discoveries and supplantation of previous ones. Abnormalities in mitochondrial function result in disordered fatty acid metabolism. Patients with fatigue and exercise intolerance have abnormal aggregations of mitochondria in their muscle tissue. Patients with weakness, mild or severe, are found to have elevated of lactic acid levels in the serum and cerebrospinal fluid (CSF) due to the reliance of the body on glycolytic function for the production of ATP rather than on the breakdown of the fatty acids. There is no effective treatment for any of the mitochondrial disorders. Attempts to supplement the diet with a variety of respiratory chain constituents, such as coenzyme Q, have met with only anecdotal success. The predominant importance of defining a syndrome of muscle weakness, exercise intolerance, and fatigue is to differentiate an organic from a psychiatric cause of impaired function in patients. Fatigue and myalgia are the predominant complaint of patients who present to the neurologist or their general physician with these diseases. It is likely that the vast majority of patients with these symptoms are initially diagnosed to have stress-related psychiatric conditions – a disservice foisted

on a small subgroup who may suffer from mitochondrial pathology.

Toxic Myopathy

Numerous toxins affect the muscle protein matrix. The most common exogenous muscle toxins are ethanol, hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, and steroids.

Ethanol Ethanol causes a direct toxic effect, raising serum CPK and causing electromyographic changes of myopathy and proximal as well as distal muscle weakness. In severe cases, myoglobinuria occurs; cardiotoxicity is common. Alcohol itself may not be the lone offender; other electrolyte disturbances and vitamin deficiencies are contributory. Abstinence from ethanol is mandatory.

HMG-CoA reductase inhibitors HMG-CoA reductase inhibitors are used commonly for lipid- and cholesterol-lowering effects, having proved to decrease the incidence of fatal myocardial infarction in patients with elevated cholesterol. Unfortunately, these drugs may also interfere with fatty acid metabolism, and muscle damage occasionally occurs with severe elevations in serum CPK, renal failure, and muscle weakness. A specific pathology has not been clearly delineated; however, abnormal energy metabolism within muscles is blamed for muscle breakdown in susceptible patients.

Steroids A number of endocrinological conditions such as thyrotoxicosis and Cushing's syndrome, as well as hypoparathyroidism and vitamin D deficiency, cause myopathy. The most common endocrinologically induced myopathy represents the toxicity of large doses of endogenous glucocorticoids to the muscle milieu.

Acute steroid myopathy Acute steroid myopathy has only recently been distinguished from chronic steroid myopathy. Groups of asthmatic patients given high doses of steroids with or without the concomitant use of nondepolarizing muscle relaxants in intensive care units were found to develop static weakness and myosin-deficiency myopathy by muscle biopsy. Weakness occurring in these conditions is independent of prolonged neuromuscular blockade. It improves. At the present time, there is only supposition as to why the combined use of high doses of steroids and the critical illness state or neuromuscular blockade prompts myosin loss. The trophic influence of the electrochemical message sent through the neuromuscular junction to muscle combined with the

catabolic effects of glucocorticoids probably combine to create this pathology.

Chronic steroid myopathy Unlike acute steroid myopathy, patients on low to medium doses of steroids for any of a number of medical conditions can become progressively weak over weeks to months. The problem tends to be proximally predominant, and the pathology of the condition involves type II muscle fiber atrophy, a similar pathology seen in patients who are chronically bedridden and not exposed to steroids.

Differential Diagnosis of Myopathy

Central Nervous System Disease

It is distinctly uncommon for diseases of the brain, brain stem, or spinal cord to cause weakness bilaterally without other accompanying symptoms, whereas muscle weakness can occur in isolation without myalgia, sensory loss, or clear serum elevations of CPK. Bilateral brain disease resulting in bilateral limb weakness or bilateral cranial nerve abnormalities generally impairs the mental status. It is this preservation of mental status in patients with myopathy that makes distinguishing myopathy from brain or brain-stem diseases simple. It is only slightly more problematic to distinguish spinal cord causes of weakness from myopathy. Mental status is preserved in spinal cord disease unless respiratory muscle function is compromised severely and hypoxemia causes delirium. Sensory loss is the rule in myelopathic disease, as well as severe bowel and bladder dysfunction. The bowel and bladder dysfunction occurring in myopathy is due more to immobilization and the inability of the patient to physically get to a bathroom than it is to any primary pathology of the detrusor or anal sphincter muscles.

Neuropathy

Neuropathy can cause unilateral or bilateral muscle weakness generally with a distal predominance; however, sensory loss occurs in most neuropathies. Very rare neuropathies, such as multifocal motor conduction block neuropathy or primary motor neuropathy from motor neuron disease or lead intoxication, can mimic myopathy, but reflexes are absent or depressed. Patients with severe myopathy may have decreased or even absent reflexes, but this is extremely rare. In difficult cases, distinguishing neuropathic from myopathic weakness depends on electrodiagnosis and muscle biopsy. It is not unusual for an individual undergoing a workup for amyotrophic lateral sclerosis, which affects the lower motor neuron, to undergo

a muscle or nerve biopsy to help distinguish benign myopathic disease from the devastating diagnosis of anterior horn cell disease. However, the majority of neuropathies cause greater distal than proximal weakness, with profound sensory loss early in the course of the syndrome, thus allowing the clinician to distinguish neuropathy from myopathy in most cases.

Neuromuscular Junction Diseases

Patients with neuromuscular junction disease may have a predominant disease of the cranial innervated musculature and present with double vision, lid drooping, dysphagia or dysarthria, or problems with neck extension. Isolated respiratory muscle weakness has also been reported, but not commonly. Extracellular calcium, responding to the action potential reaching the end of the motor nerve, enters the presynaptic nerve through voltage-sensitive channels, causing the vesicles of acetylcholine to couple with the nerve membrane, releasing acetylcholine as the chemical message; this results in muscle contraction in the postjunctional area. Botulinum toxin envenomation creates a condition in which toxin enters the prejunctional membrane, preventing acetylcholine vesicles from coupling with the prejunctional nerve membrane, aborting the message for the muscle to contract. This condition results in the degeneration of this part of the nerve; in a sense, botulinum toxin envenomation not only causes a neuromuscular junction short circuit, but actually causes a distal motor neuropathy. Patients generally need months to regrow this part of the nerve.

Lambert-Eaton syndrome is the prototypic autoimmune disease in which antibodies are raised to voltage-gated calcium channels. Molecular mimicry among moieties on small-cell carcinomas and the prejunctional neuromuscular junction membrane creates a situation whereby the host raises antibodies both to small-cell cancer and the prejunctional membrane, resulting in an attack on the cancer and the fluctuating weakness seen as calcium inefficiently enters the prejunctional neuromuscular junction membrane due to competitive inhibition by these antibodies.

Most postjunctional neuromuscular diseases are the result of abnormalities induced in the coupling of acetylcholine to its receptor in the postjunctional membrane or in abnormalities of the acetylcholine receptor itself. Iatrogenic neuromuscular junction blockade occurs with the use of depolarizing or nondepolarizing muscle relaxants. The autoimmune disease myasthenia gravis results in inefficient neuromuscular transmission and weakness due to abnormalities in the acetylcholine receptor through competitive inhibition by autoantibodies. Similar to

the Lambert-Eaton syndrome, myasthenia gravis can be treated with a number of immunomodulating agents such as steroids or with the removal of exogenous antibody through plasma exchange or through other forms of nonspecific immunosuppression. Many patients have been thought to have conversion reaction because weakness can be subtle. Exogenous stressors such as the flu can stress the neuromuscular junction and cause even more inefficient neuromuscular communication, resulting in fluctuating weakness. Some victims are treated for psychiatric disease, delaying proper treatment.

Myopathy

Myopathy is generally characterized by mild to moderate elevations of the CPK level, greater proximal than distal muscle weakness, with the preservation of deep tendon reflexes and no sensory loss. The varieties of myopathy have already been discussed.

Electrodiagnosis

The proper designation of weakness as originating in the muscle can be made noninvasively through clinical examination and then confirmed through the electrodiagnostic capabilities of electromyography and nerve conduction studies. Using our knowledge of the anatomy of the muscle and recruitment of muscle fibers in the development of muscle contractions, we can evoke patterns of responses from muscles with a needle electrode for quick and efficient disease localization.

Using the principle of differential amplification, a needle electrode with two active recording surfaces separated by an insulator is introduced superficially into muscle. Recording the difference in voltage between the two active surfaces, a simple wave form is generated during contraction. The muscle cell group that contracts, innervated by one particular motor neuron, is termed the motor unit. As the muscle contraction is maintained voluntarily by the patient, a repeating waveform appears on the oscilloscope. Minimal contraction is necessary for this waveform to appear repetitively, up to 5–15 times s^{-1} . As the individual increases the force of the contraction, another motor unit is recruited to increase muscle tension, and another waveform appears on the screen, twitching between 5 and 15 Hz. Because there are hundreds of motor units in a typical muscle, hundreds of motor units appear and create a pattern of discharge on the oscilloscope. In patients with nerve disease, the number of motor neurons is decreased. Therefore, the number of motor units recorded on the screen is decreased. If the nerve disease has been occurring

Figure 1 Successive decreases in waveform amplitude during repetitive stimulation testing in a patient with myasthenia gravis.

long enough, the muscle cells that were served by the damaged nerve in question will have been reinnervated by the remaining normal nerves; then each of the waveforms seen will be larger than generally expected. In addition, the rate at which each motor unit contracts is much faster than the normal 5–15 Hz. Neuropathy is then the likely diagnosis.

In contrast, in myopathy the number of motor units remains the same, but the number of muscle cells contracting effectively decreases. Assuming that a random distribution of muscle cells either have died or are damaged significantly, then each resulting motor unit creates a smaller waveform on the electromyographer's oscilloscope. In addition, because a contraction of the weak muscle, even to a moderate extent, necessitates the recruitment of motor units to maintain the same force as in a normal muscle, the contraction pattern appearing on the oscilloscope appears to be that of a maximum voluntary contraction, even though full voluntary contraction has not yet been achieved. Myopathy is then the likely diagnosis.

The repetitive stimulation method may distinguish myopathy from disorders of the neuromuscular junction. Repetitive nerve stimulation results in numerous recorded compound motor action potentials (Figure 1). In the case of neuromuscular junction disease, however, either too little or varying amounts of acetylcholine are released at the neuromuscular junction and fewer muscle cells contract. Less force is generated in the muscle, which expresses itself as weakness clinically and as a decrease in waveform amplitude, as shown in Figure 1.

Muscle Biopsy

It is through sophisticated staining methods of muscle tissue that our understanding of the myopathic

conditions has shifted since the mid-1980s. This has resulted in more accurate diagnoses and in the discovery of new forms of myopathy. Undoubtedly, additional forms of myopathy and a further sub-specification of disorders now lumped together under one designation will be discovered in the near future. One example of this is IBM, which was previously thought to be a steroid-unresponsive form of polymyositis and now enjoys its own designation as a separate disease entity, largely due to sophisticated histopathological techniques.

Therapy

Muscular dystrophies by definition are designated untreatable. Gene therapy trials will probably remove this untreatable designation. At the present time, physical rehabilitation is really our only means of keeping patients with muscular dystrophy as strong as possible. In the case of myotonic muscular dystrophy, in which weakness is generally not the worst problem, the avoidance of late-stage complications such as heart block and respiratory compromise from central neurogenic hypoventilation is the rule. In the case of glycogen-storage diseases, in which the avoidance of sudden exertion and dehydration helps best, genetic counseling is our only other means of prevention. The therapeutic armamentarium in myopathy, however, is greatly widened when we address inflammatory myopathy.

Corticosteroids

Corticosteroids prevent the mobilization of plasma cells and communication among a variety of white blood cells by decreasing interleukin production, minimizing inflammatory reactions and subsequent muscle destruction. This form of immunosuppression is still considered nonspecific in that no one particular process of the immune response is knowingly targeted. Prednisone is the mainstay of treatment for dermatomyositis, polymyositis, and the immune-mediated myopathies accompanying collagen vascular diseases such as systemic lupus erythematosus and rheumatoid arthritis.

However, the previous discussion of steroid-induced myopathy, whether acute or chronic, should not be taken lightly. The very treatment for these myopathies may precipitate a chronic form of weakness and, therefore, the steroid dosage necessary to prevent weakness should be titrated downward to the lowest effective dose. Alternate day therapy may slightly decrease the incidence of steroid myopathy and other abnormal side effects such as ulcer disease, cataract formation, glaucoma, hypertension,

diabetes, and aseptic necrosis of the hip, as well as severe weight gain from lipogenesis. Many inflammatory myopathies burn out and do not need to be treated for more than 2–3 years. Even this length of time may create enough of an opportunity for untoward side effects to occur.

Intravenous Immunoglobulin

Intravenous immunoglobulin (IgG) has failed to show significant results in polymyositis; however, some cases of dermatomyositis stabilize or improve with the use of pooled IgG. Perhaps it is because dermatomyositis is a B-cell-, plasma-cell-, and antibody-mediated disease that the application of large quantities of anti-idiotypic and nonspecific antibodies act as competitive and non-competitive inhibitors, blocking pathogenic host antibodies from destroying muscles. IgG is used more for other causes of weakness at other locations in the neuroaxis, such as the neuromuscular junction in the case of myasthenia gravis, and for Guillain-Barré syndrome, an inflammatory proximal neuropathy.

Plasmapheresis

The removal of plasma proteins, cytokines, and immunoglobulins and their replacement either with another individual's plasma or with an albumin and saline solution has been used in other immune-mediated conditions, both neurological and non-neurological. A controlled trial of plasma exchange in patients with polymyositis and dermatomyositis failed to show any benefit, however.

Conclusion

Current medications are helpful but are also toxic when used chronically, so although medical science can provide benefits for some clearly defined myopathic syndromes, we can expect more clinical trials of other pharmaceuticals. The variety of myopathies mirrors the variety of diseases in other parts of the

neuroaxis. Genetic influences, environmental influences, immunological influences, and toxic causes of weakness clearly illustrate the vulnerability of muscle tissue to a variety of stressors. However, psychic stress does not cause weakness. It can create fatigue, but clearly it does not create a consistently measurable abnormality of force generation due to muscle damage or neuromuscular junction disease. Therefore, weak patients need to be worked up for organic diseases. The complicated structure of nerve, neuromuscular junction, and muscle allows for breakdowns at any point along the way, and many diseases result, some of which have been clearly defined; all of which are measurable as weakness at the bedside, in the electrophysiology laboratory, and pathologically.

The physiological muscle response to numerous exogenous and endogenous stimuli may be normal contraction, paralysis, or anatomic disruption. The most explicit exposition of stress affecting muscle occurs in acute steroid myopathy, in which normal contraction may be affected to the point of paralysis without anatomic disruption of the muscle membrane and intracellular contents. In addition, acute steroid myopathy may also express its severity in myosin dissolution and the eventual anatomic disruption of the muscle membrane. This form of toxic myopathy best illustrates the effects of stress on muscle.

Effector cells
NK cells

NK cells that induce lysis of target cells. A subpopulation of lymphocytes characterized by the expression of surface markers that are distinct from those present on T or B lymphocytes. NK cells have a unique capability to recognize and eliminate a broad range of abnormal cell targets without prior sensitization. They are components of innate immunity responsible for immune surveillance against infectious agents and transformed cells.

NK-cell assay

An assay used to measure NK activity by coincubation of effector (E) with radioactively labeled target (T) cells at several different E : T ratios. The assay estimates the percentage of specific lysis attributable to NK cells based on levels of radioactivity released from a defined number of target cells.

Glossary

Activated
NK cells

A subset of NK cells responding to stimulatory signals that have upregulated expression of receptors for interleukin-2 as well as other surface molecules and have acquired new functional attributes that facilitate cellular interactions.

Antibody-
dependent
cellular
cytotoxicity

A form of cell death mediated by NK cells in the presence of an antibody that is specific for an antigen expressed on the surface of target cells and decorates the NK cell through binding to a receptor for immunoglobulins. This antibody forms a bridge between effector and target cells.

Cytotoxicity

One of the functions of NK cells commonly used for assessing the level of NK activity in the peripheral blood, other body fluids, or mononuclear cells isolated from tissues.

Characteristics of Natural Killer Cells

NK cells are effectors of the innate immune system that play an important role in host response against viruses and tumor cells through the production of cytokines and direct cytolytic activity. Unlike other effector cells, NK cells are able to kill these targets spontaneously, without having had prior encounters with them. NK cells also appear to be highly sensitive to stress, exhibiting dramatic changes in function in response to acute or chronic stress. Because they appear to be involved in important immunological defense against infectious agents and against cancer, and because they are affected so readily by stress or emotional state, NK cells have been a well-studied variable in the stress–illness relationship.

Natural killer cells were first described in the early 1970s based on their functional capability to lyse

tumor cells in the absence of prior stimulation. This characteristic of NK cells was considered to fit their role as mediators of immune surveillance. Since then, NK cells have been shown to mediate other biologically important functions. NK cells are now known to produce cytokines that regulate the development of acquired specific immunity, play a role in the rejection of bone-marrow grafts, be responsible for the selective elimination of abnormal cells, and be implicated in the development of autoimmune diseases and the graft versus host disease (GVHD).

NK cells make up from 10 to 15% of human peripheral blood lymphocytes, as determined by phenotyping using labeled monoclonal antibodies (MAbs). NK cells can home to secondary lymphoid organs. It is estimated that approximately 5% of mononuclear cells in uninflamed lymph nodes are NK cells, and they constitute 0.4–1% of the lymphoid cells found in inflamed tonsils and lymph nodes. Thus, the extravascular lymphoid tissues represent a large pool of innate effector cells because, in aggregate, lymph nodes harbor 40% of all lymphocytes, whereas peripheral blood contains only 2%.

NK Cell Development and Subsets

NK cells originate in the bone marrow from CD34+ hematopoietic progenitor stem cells and require the bone marrow microenvironment for complete maturation. In the presence of stromal cell-derived growth factors, c-kit ligand and flt-3 ligand, the CD34+ stem cells acquire the surface receptor for the cytokines interleukin (IL)-15/IL-2. The acquisition of the IL-15/IL-2 receptor renders the NK progenitors (NKP) responsive to IL-15, a critical cytokine for NK cell development. The next steps of development involve the acquisition of the unique NK cell receptor repertoire and proliferation into phenotypically and functionally mature NK cells.

Two subsets of NK cells are present in the peripheral blood of healthy adults. The majority of NK cells express low levels of CD56 (CD56^{dim}) and high levels of Fcγ receptor III (FcγRIII, CD16^{high}), whereas 10% of NK cells are CD56^{bright} CD16^{dim/−}. In the lymph nodes, the majority of NK cells belong to the NK-cell bright subset. These two NK subsets differ in receptor expression, trafficking, cytokine production, and the ability to mediate cytotoxicity. CD56^{dim} NK cells are more cytotoxic and mediate higher antibody-dependent target cell lysis but produce low levels of cytokines (Table 1). In contrast, CD56^{bright} NK cells can produce abundant cytokines, but exert low natural cytotoxicity and antibody-dependent cellular cytotoxicity (ADCC).

Receptors

The triggering of NK cell cytotoxicity is determined by the balance of activating and inhibitory signals received via the broad repertoire of receptors found on individual NK cells. These receptors monitor the interactions of NK cells with other effector cells of the immune system and with cellular targets (Figure 1). In humans, there are three main classes of receptors: natural cytotoxicity receptors (NCRs), killer immunoglobulin-like receptors (KIRs), and killer C-type lectin receptors.

The NCRs, which bind to as yet unidentified tumor antigens, are all activating receptors and have been demonstrated to be involved in the NK-cell-mediated killing of various cancer cell lines. Three NCRs (NKp46, NKp44, and NKp30) have been identified. NKp46 and NKp30 are constitutively expressed by all peripheral blood NK cells and are not found on other immune cells. NKp44 is not expressed by resting NK cells, but is upregulated by IL-2 stimulation.

The KIRs belong to the immunoglobulin superfamily. There are two functionally distinct sets of KIRs: inhibitory and activating. KIRs specifically recognize major histocompatibility complex (MHC) class I alleles, including groups of HLA-A, -B, and -C molecules. Each specific set of inhibitory and activating KIRs has an identical extracellular domain and, consequently, each set binds to identical ligands. However, because of differences in their cytoplasmic domains, one set of KIRs signals an inhibitory response and the other set signals an activating response following their

Figure 1 Natural killer cell cytotoxicity. a, No lysis; b, lysis. NK cell cytotoxicity depends on a delicate balance between activating and inhibitory receptors. The presence of activating receptors and inhibitory receptors on the surface of NK cells is necessary to protect normal cells from lysis. Inhibitory signals normally predominate over activating receptors, and a cell able to induce such signals (e.g., through expression of abundant MHC molecules) avoids lysis. This process occurs constantly as NK cells survey normal host tissues. However, when activating receptors engage their ligands on target cells in the absence of inhibitory receptor–ligand interactions, a net activating signal is generated, resulting in lysis of the target. Virally infected or tumor cells downregulate ligands that are recognized by the NK-cell inhibitory receptors (i.e., MHC molecules) and, thus, NK cells are able to recognize these targets as nonself and to kill them.

binding to identical MHC class I alleles. Inhibitory KIRs usually have a higher affinity for MHC-class I ligands and, therefore, coligation of both activating and inhibitory receptors results in a net negative signal. Presumably, this double set of receptors with opposing signaling properties exists to regulate NK activity and to protect normal cells from being eliminated.

The killer C-type lectin receptors include inhibitory heterodimers of CD94 complexed with NKG2A or NKG2B and activating heterodimers complexed with NKG2C or NKG2E. These receptors all recognize the overall expression of MHC class I, in that they bind to HLA-E, which is expressed only in association with MHC leader peptides. Another activating C-type lectin receptor, NKG2D, is expressed as a homodimer that binds to peptides associating with the stress-inducible molecules MIC-A, MIC-B, or ULBPs.

In addition to the various activating and inhibitory receptors, NK cells express several receptors that play an important role in enhancing their interaction with target cells and enhancing the NK-cell-mediated cytotoxicity (Table 2).

Mechanisms of Cytotoxicity

NK cells possess a unique capacity for recognizing and killing a broad range of abnormal targets such as virally infected or transformed cells and certain allogeneic targets. Although the molecular events involved in the process of target recognition and

signaling are not fully known, the cellular alterations that result from effector (E) cell–target (T) cell interactions have been identified. NK cells can use two different mechanisms for killing, and several distinct sequential steps are involved in the process of target cell lysis.

- *Perforin-mediated cytotoxicity.* NK cells can lyse target cells through a calcium-dependent release of intracytoplasmic granules containing perforin or granzymes A and B. This secretory activity mediated by perforin/granzyme release results in necrosis and is directed primarily at NK-sensitive targets, such as K562 tumor cells. Perforin forms pores in target cells, whereas the granzyme release is necessary for target cell killing.

- *Induction of apoptosis through death receptors.* Activated NK cells express the Fas ligand (FasL) and can kill Fas+ (CD95+) targets through the activation of enzymes that fragment DNA. In addition, NK cells express tumor necrosis factor (TNF)-related apoptosis-induced ligand (TRAIL) and can thereby activate apoptosis in cells that express TRAIL receptors, including death receptor 4 and death receptor 5. Nonsecretory NK activity (surface receptor-mediated apoptosis) is preferred for NK-resistant targets such as fresh tumor or solid tissue cells.

Activated NK cells can rapidly kill a number of targets by combining these two mechanisms. NK cells that survive a lytic event are able to recirculate and can bind to another susceptible target and kill it. The efficiency of NK cell-mediated lysis (killing) is dependent on the ratio of NK cells to abnormal cells and on the level of NK-cell activation.

Biological Importance of NK Cells

NK cells participate either directly or indirectly in a variety of essential biological processes, ranging from reproduction to immunoregulation (Table 3).

Defense against Infections

The major function of NK cells appears to be defense against infection. They have been shown to mediate antiviral, antifungal, and antibacterial activities *in vitro*. NK cell importance in the control of infections *in vivo* is supported by studies of experimental viral infections in mice and by reports correlating low NK activity with increased sensitivity to frequent and severe viral infections in humans, including herpes simplex virus (HSV), Epstein–Barr virus (EBV), and cytomegalovirus (CMV) infections. *In vivo* responses of NK cells to a viral challenge involve increases in cytotoxicity, proliferation, migration of NK cells to infected tissues, and production of interferon (IFN)- γ by NK cells. Virus-induced interferons increase NK cell functions and also modulate IL-12 expression, contributing to the development of an antiviral milieu early on during infection and prior to the appearance of virus-specific T cells. Activated NK cells may reduce viral replication by killing infected host cells, and they are able to produce a variety of cytokines that can inhibit viral replication as well as facilitate antigen processing or antigen presentation by increasing the expression of MHC molecules.

Antitumor Effects

NK cells were first discovered because of their ability to kill *in vitro* certain tumor cell lines. Subsequently, NK cell antitumor activity has been convincingly demonstrated in several animal models of cancer and metastasis. These experimental studies suggest that activated NK cells play an important role in limiting both local tumor growth and dissemination of metastases. In particular, activated NK cells are thought to be responsible and ideally suited for antitumor surveillance because they appear to be able to enter solid tissues, migrate to sites of metastasis, and eliminate malignant targets while sparing normal tissue cells. The depletion of NK cells from animals enhances the *in vivo* growth of implanted tumor cells, whereas the

administration of NK cells to animals with metastatic cancer eliminates the tumor and prolongs survival. In a prospective study following 3500 Japanese over 11 years, the incidence of cancer was significantly increased in those with lower initial NK cytotoxic activity. In gastric and colon cancer patients, lower NK cytolytic activity at diagnosis correlated with higher tumor volume, metastases, and a worse prognosis. These data suggest that an adequate NK cell number and levels of NK activity are needed to mediate immune surveillance against malignancy.

Regulation of Immunity

NK cells can exert immunoregulatory activity through their interactions with other immune effector cells and by producing several cytokines, bridging innate immunity with adoptive immunity. Recently, dendritic cells (DC) have been implicated in the activation of NK cells. The activation of NK cells by DCs may play a role in shaping the emerging adaptive responses.

NK cells are constantly primed for activation by normal host cells, but their activation is negatively balanced by the inhibitory receptors that recognize self MHC class I antigens. A loss of this self-inhibitory mechanism could lead to both cytotoxicity and cytokine release by NK cells and may play a role in autoimmunity. Alterations in NK cell functions have been described in patients with autoimmune diseases. Such patients may have low levels of natural killing due to both reduced levels of circulating NK cells and defects in lytic activity.

Measurement of NK Cells

The measurement of NK cells in body fluids or cell suspensions consists of determinations of the NK cell number and NK activity. Both are necessary for an adequate evaluation of natural immunity or for following its changes during disease or in response to stress. In most instances, the level of NK activity per cell is the best estimate of the functional potential of NK cells.

NK cell numbers are generally measured using monoclonal antibodies specific for NK cell-associated markers (e.g., CD56 and CD16 in humans, NKR-P1 in rats, and NK1.1 in mice), which are labeled with a fluorescent dye. Following staining, the percentage of positive cells in a population is determined by flow cytometry; this percentage value is then converted into the absolute number of NK cells based on the simultaneously obtained differential lymphocyte count. Or, in a single-platform flow cytometry method, fluorosphere beads are used to allow for the direct calculation of the stained NK cells in a tube.

Natural killer activity has been traditionally measured in short-term (4-h) ^{51}Cr release assays, in

which a standard number (5×10^3) of cultured K562 cells is used as radiolabeled targets (T) and peripheral blood mononuclear cells as effectors (E). The latter are adjusted in number to give at least four different E : T ratios in the assay. This allows for the generation of a lytic curve by plotting the percentage of specific lysis against the E : T ratio. More recently, flow cytometry methods have been introduced that simultaneously measure NK-cell cytotoxicity and NK-cell phenotype. These methods are gaining acceptance because they dispense with radioactivity, are cost effective, and offer an opportunity to evaluate several distinct characteristics of effector cells. However, these methods have not yet been validated against the Cr-release assay, which remains the gold standard for measuring NK activity. The results of NK-cell assays are usually expressed as lytic units (LU) calculated from the lytic curve and defined as the number of E required to kill 5×10^3 targets in a batch of tested cells. Computer programs are available to facilitate the transformation of these data.

NK Cells in Human Disease

NK cell abnormalities either in NK-cell number or activity have been described in human diseases. In either case, only chronic abnormality in NK cell activity or number is considered to be pathological because transient changes accompany a variety of physiologically normal events (e.g., circadian variations, daily stress, exercise, or a common cold). Although the absolute number of NK cells in the peripheral circulation may be significantly below or above a normal range, this does not mean that NK activity is also abnormal. Often, individuals with a low number of NK cells have normal NK activity because their NK cells are activated. Conversely, some individuals with a high NK cell number may have little NK activity due to a lack of or low function of these cells. Therefore, to evaluate the functional potential of NK cells appropriately, it is necessary to measure both NK-cell number and NK activity and to express NK-cell functions on a per cell basis.

Chronically low levels of NK cell activity are seen in cancer, acquired or congenital immunodeficiency diseases (e.g., AIDS), severe life-threatening viral infections (HSV, EBV, and CMV), a subset of patients with chronic fatigue syndrome (CFS), certain autoimmune diseases (e.g., connective tissue diseases), and behavioral disorders (e.g., depression). Persistently elevated NK cell activity is relatively rare, being reported in autoimmune liver disease (including viral hepatitis) and in NK-cell lymphoproliferations. The latter present as elevations in the number or activity of NK cells or both and are characterized by a benign course,

lymphocytosis of large granular lymphocytes (LGL), cytopenias, and splenomegaly. Rare acute proliferations of LGL have been reported and are consistent with aggressive leukemia/lymphoma.

Persistently low levels of the NK-cell number or activity in patients with advanced metastatic or other diseases may be associated with more severe symptoms or an increased risk of disease progression. Therefore, it may be advantageous for patients with chronically low NK cell activity to receive therapy designed to augment NK cell functions. Such therapies are available and consist of the administration of agents known to upregulate endogenous NK activity (e.g., interferons, IFNs; IL-2) or an adoptive transfer of autologous A-NK cells, either systemically or regionally. These therapeutic strategies have not been extensively evaluated, however. More recently, adoptive transfers of NK-92, an NK-cell line established from a patient with non-Hodgkin's lymphoma, have been used in the therapy of hematological malignancies and solid tumors with acceptable toxicity and the goal of providing the host with an excess of antitumor effector cells able to eliminate tumor cells.

NK Cells and Aging

The cells of the immune system are constantly renewed from hematopoietic stem cells. With age, a reduction in the overall capacity for the renewal of these stem cells as a whole has been observed. Unlike T and B cells, the absolute number of NK cells is increased in older individuals compared to young or middle-aged groups, and IFN- γ production and phagocytosis are also increased. Total NK-cell cytotoxicity is stable, however, so the NK-cell cytotoxicity on a per cell basis is impaired in older individuals, as is the response of NK cells to IL-2. The age-associated increases in the number of NK cells and in T cells expressing NK receptors might reflect an alteration in regulatory mechanisms that favors NK-cell functions associated with the regulation of immune responses at the expense of antitumor functions, for example.

Stress and NK Cells

Interactions between NK cells and neuroendocrine systems have received increasing attention. NK cells express receptors for neuropeptides, opioids, prolactin, and other neurohormones, which regulate interactions between the brain and the immune system. Therefore, NK cells are highly responsive to changes in the serum levels of these hormones. Stress often involves all these hormones, and the effects of stress on the immune response can be monitored by serially following changes in NK cell activity.

For example, major stressful life events in otherwise healthy individuals are generally associated with low NK cell activity. However, this effect of stress on NK cells is dependent on several other variables, including the duration of a stressful event, how long afterward responses are measured, and variables that affect the intensity of stress experienced.

Several studies have addressed effects of stress on NK cells and have begun to identify mechanisms underlying these effects. These studies have examined stress effects on overall NK activity, on the number of NK cells in circulation, and on the level of activity per NK cell. NK cell numbers tend to change as NK cells leave the bloodstream and migrate into tissue or lymph nodes. Stress-related changes in cell numbers and activity reflect this process, and thus NK activity per cell is the most reliable way of measuring the effects of stress on these cells.

Two primary systems are involved in the regulation of stress: the sympathetic nervous system (SNS) and the hypothalamic-pituitary-adrenocortical (HPA) axis. SNS activation is initially achieved through neural stimulation and is more or less immediate. Measurable increases in organ or system function tied directly to SNS activation (e.g., heart rate) can be detected within 1 min after the onset of a stressor. Endocrine activity, principally catecholaminergic, intensifies and extends the duration of neural stimulation, and the release of epinephrine and norepinephrine from the adrenal medullae and sympathetic neurons is reliably associated with stress.

The effects mediated by the HPA axis, which culminate in the increased release of glucocorticoids (i.e., cortisol) from the adrenal cortexes, are slower to act or to recover. Ordinarily, changes in HPA activity are not detectable for several minutes, but once initiated, they may persist for hours. This suggests that initial or acute stress responses are governed principally by the SNS, which may have a stimulatory effect on NK activity or may affect cell migration (more NK cells released into circulation). In general, acute stress lasting as little as a few minutes is associated with large, rapid increases in NK-cell number in peripheral blood circulation and a corresponding increase in overall cytotoxicity. Chronic stress lasting days, weeks, or months appears to be associated with the suppression of NK-cell number and cytotoxicity (Table 4). Differences in how acute and chronic stress affect NK cells provide some insight into the mechanisms, functions, and consequences of stress modulation of NK activity, as outlined briefly in the following section.

NK Cells and Acute Stress

Acute stress is almost always associated with a rapid release of catecholamines, leading to an immediate increase in NK-cell number in the peripheral

Table 4 Summary of the effects of acute and chronic stress in human NK cells^a

circulation, probably due to changes in NK-cell trafficking (i.e., increased movement from lymphoid or nonlymphoid tissue into the peripheral circulation as a result of a reduction in NK cell adherence to endothelial cells combined with an increase in blood flow). This increase in the number of NK cells is accompanied by increases in individual cell function, as observed in some studies but not in others. However, an acute elevation of glucocorticoids within 10–20 min after stress causes immune cells to marginate and subsequently to enter target tissues, probably as a result of the local release of cytokines, which act as chemoattractants. Hence, the enhancing effect of acute stress on immune cells is short-lived and is followed by a suppression of NK cell activity that may be unrelated to changes in NK-cell number. These effects have been observed in naturalistic studies of tandem parachute jumpers and in laboratory studies using far less severe stressors. In numerous studies, the time course of acute stress on NK-cell number appears to be biphasic, increasing on the initial encounter with stress and decreasing rapidly to the baseline resting level or below as soon as the stressor is terminated. Thus, NK-cell-enhancing effects of acute stress are reversible. Age, social support, time of day, and other variables appear to modulate the influence of acute stress on NK cells. The acute reactivity of NK cells during or shortly after an acute stressor may be correlated with levels of SNS activation (e.g., epinephrine and norepinephrine levels) and varies across the time of day. It has been observed that the most labile responses in NK cell activity occur late in the afternoon. A variety of measures thought to completely or partly reflect sympathetic arousal, including blood pressure and stress hormone levels, have been correlated with changes in NK-cell number and function.

The available studies underscore the complexity of acute stress responses and factors determining NK activity. They also suggest that the regulation of immune responses to acute stress depends on both catecholamine and cortisol phases of the response.

Furthermore, there may be several other pathways (e.g., those involving modulation by endogenous opioids) by which acute stress might affect the activity of NK cell.

NK Cells and Chronic Stress

Chronic stress, involving the repeated or sustained elevation of stress hormones, appears to suppress NK cell activity as well as the number of cells in circulation. For example, studies of medical students at the time of low and higher stress periods confirmed that NK cells were suppressed during prolonged stress. Similarly, studies of caregivers for Alzheimer's disease patients and of bereaved populations also provide evidence of chronic suppression of NK cell activity. In one study, bereaved women exhibited lower NK cell activity than nonbereaved participants, and in another study, caregivers were observed to have lower NK cell activity and increased plasma cortisol concentrations than controls. Studies of disasters, such as earthquakes or nuclear accidents, have also provided evidence of a lower number of NK cells in stressed groups, particularly if participants reported greater worry, intrusive thoughts about the disaster, or general persistent distress. Depression in young adults is associated with depressed NK activity. The effects of chronic stress on NK cells are clearly different from those of more short-lived acute stress, and it is possible that the suppression of cytotoxicity, cytokine release, and/or the NK-cell number observed in chronic stress is due to more slowly acting hormonal systems. It appears that long-term (i.e., chronic) responses to stress are also likely to be characterized by SNS and HPA activity, but the latter is thought to exert predominantly suppressive, nonreversible influences on the immune system. Lasting stress also appears to deplete the number of NK cells in blood, although it is not clear where these cells go when they have left the bloodstream or how these changes differ from the reversible effects of acute stress. The potential mechanisms responsible for these long-term effects are presently unknown. Nevertheless, the potential consequences of having persistently low NK cell activity related to chronic stress may represent a health hazard, although no direct relationship has been established so far between disease development and chronically low NK activity.

NK Cells and Cancer

Based on NK cell responsiveness to stress, many studies have used NK activity as a biomarker of stress, attempting to correlate it with health, disease, and the ability to cope with life. This is particularly evident in studies linking stress and depression with

development of cancer. By and large, these studies were performed with small cohorts of patients and yielded conflicting results. Although the literature dealing with the involvement of stress in cancer development, cancer progression, or response of cancer to treatment is extensive, few large-cohort investigations of immune surveillance and stress are available. In one such study of 6284 Jewish Israelis who had lost an adult son, there was an increased incidence of melanoma in the parents of accident victims and war casualties relative to nonbereaved members of the population. Unfortunately, no NK-cell numbers or activity was measured in this study. Because stress and depression have been linked with the altered cytokine profile (e.g., increased pro-inflammatory cytokine production), downregulation of MNC class I and class II molecules, and reduced NK activity in numerous studies and because the same biological effects accompany cancer progression, the tendency has been to seek correlations among stress, NK activity, and cancer and to speculate that NK activity may be a surrogate marker linking stress to cancer. However, inconsistent preliminary data and a lack of prospective long-term studies in large cohorts of humans do not at this time permit the conclusion that NK activity can be considered a biomarker of stress or a biomarker of cancer development progression.

Definition of Negative Affect
 Role of Negative Affect in Stress Research
 Conceptual Issues
 Measurement

Glossary

<i>Arousal</i>	A state of activation, surprise, and intensity.
<i>Circumplex model</i>	A dimensional approach to mood wherein two independent dimensions are crossed to form a two-dimensional space encompassing all mood states.
<i>Negative affectivity</i>	A stable personality characteristic associated with high levels of negative mood; sometimes referred to as trait negative affect or neuroticism.
<i>Positive affect</i>	Experiences high in the qualities of joyfulness, happiness, pleasantness, and cheerfulness.
<i>Specific affect model</i>	Position that there is a limited set of distinctive moods that do not fall along one or two dimensions.

Definition of Negative Affect

Negative affect refers to a set of states that fall into the broad class of phenomena known as mood, emotion, and affect. Emotions and affects sometimes refer to shorter fluctuations than mood (minutes versus hours), although these terms are often used interchangeably. These terms all refer to constructs that include subjective feelings, behavioral changes, and physiological states, and the majority of research on negative affect has focused on subjective states. Surprisingly, there are only weak to moderate associations

among subjective, behavioral, and physiological indicators of mood. Research in the field of psychophysiology, for instance, has found that facial expressions associated with an affective state (say anxiety) are only moderately correlated with the subjective experience of either anxiety or physiological activation. This suggests that the three domains of mood may be measuring somewhat different aspects of the construct.

The functions of moods and emotions have been debated since Darwin, but most theorists agree that emotions have a strong biological basis, assisting in the preparation, shifting, and maintenance of action. In everyday life, individuals often assign emotions a primary role when describing the causes of their behavior. In addition to action, emotions and mood can also influence attention and memory. Emotional arousal, for example, may narrow attentional focus, and the recall of certain memories may be mood-dependent. While there is considerable debate about the function and definition of mood, for this article, we will largely focus on the subjective component of negative affect because this is the most common and useful definition available. Also, using a multidimensional definition of mood results in a tremendous overlap with other components of the stress model (namely, the environmental and physiological aspects of stress).

Role of Negative Affect in Stress Research

In order to understand the importance of negative affect in stress research, we first place it in the context of a general model of stress. As earlier articles of this work have shown, there are different conceptual models for thinking about stress. One model states that environmental changes interact with individuals' predisposing psychological states to produce a subjective experience and a concurrent set of physiological changes. Some stress theorists focus entirely on alterations in the environment to define stress, for example, using life events to define stress. Other theorists focus on the resulting physiological states; a good example of this is the seminal work of Hans Selye. Still other theorists base their definition of stress on the subjective

perception of stress, which is the underlying conceptualization used in the Perceived Stress Scale.

Clearly, the latter definition of stress is closely linked to the construct of negative affect. It is difficult to imagine an individual reporting that they are feeling stressed, out of control, and unable to cope, yet not feeling high levels of negative affect at the same time. In a similar vein, it is difficult to imagine how the undesirable events that environmentalists use to define stress would not invoke negative affect. Death of a loved one is a major life event that has been used to define stress, and certainly negative affect is associated with mourning the death of a loved one. However, theorists who define stress as any alterations in one's environment (even positive ones) would not necessarily require associated alterations in negative moods.

Conceptual Issues

Behavioral scientists have devised several ways of measuring negative affect and the more general concept of mood. These range from single-item measures that are anchored with positive and negative descriptors at opposite ends of the scale to much more complicated, multidimensional adjective checklists. Several conceptual issues need to be discussed to place assessment methods in an appropriate context.

Structure of Negative Affect

The first issue pertains to the structure of mood. Two opposing views have emerged about how to best represent structure, namely, the specific affect approach and the dimensional approach. The specific affect approach views mood as being made up of a number of distinct states that, though related to one another, have distinguishing characteristics. According to this approach, different negative affects are associated with unique patterns of physiological activation, for example, the type of arousal associated with fear differs from that associated with anger. Both of these states are considered negative affect, yet each is associated with a distinctive pattern of subjective, physiological, and facial characteristics. In contrast, the dimensional approach rejects the idea of specific affects in favor of a limited number of core affective dimensions. One of the dimensions often discussed concerns the degree of negativity. The most developed dimensional model is based on two affective dimensions that are crossed to yield a two-dimensional space. Like primary colors mixed together in order to create a vast array of hues, the moods in this two-dimensional space are each composed of a mixture of positive and negative affect. Within the dimensional

approach to mood, there are differing viewpoints concerning how to label the dimensions and create the two-dimensional space. Watson and Tellegen advance the position that positive affect and negative affect are the two core dimensions, whereas Russell advances the position that a single bipolar dimension of positive/negative is crossed with a unipolar activation dimension. Both viewpoints have support in the literature and scales based on each approach are currently in use.

Regardless of the specific dimensional labels used, poles of the dimensions are typically anchored with representative adjectives. The pleasant pole is generally indicated with adjectives such as happy, delighted, glad, cheerful, warm-hearted, and pleased, whereas the unpleasant pole is often marked with adjectives such as unhappy, miserable, sad, gloomy, and blue. Proponents of the activation dimensional construct label the high activation end with words such as aroused, astonished, stimulated, surprised, active, and intense, whereas the low activation end is marked with words such as quiet, tranquil, still, inactive, idle, and passive.

Content of Negative Affect

The second conceptual issue concerns the way people experience and recall their moods. When asked to report about their moods over a distinct period of time, for example, the last day or week, do people report about the frequency of their moods or do they report about the intensity of their moods? This question was addressed in a study by Diener and colleagues. By varying instructions on a mood checklist, they found that reports of mood intensity were not related to reports of mood frequency, indicating that frequency and intensity are two different ways of conceptualizing mood. From an applied perspective, when people are asked in a more general way how their mood was over the last day or over the last week, it is not clear whether they are reporting about the frequency or intensity. This ambiguity requires future research in order to facilitate interpretation of mood assessments.

Recall of Negative Affect

A third conceptual issue concerns individuals' abilities to recall mood states and whether reports of mood over long periods of time are accurate. Research on autobiographical memory has shown that there are a number of biases that occur in retrospective recall. For example, comparisons of momentary (immediate) and retrospectively recalled moods suggest that rather than providing an accurate summary of moods, retrospective reports are heavily based on

more recent experiences. Several other biases in the recall of mood have been identified, leading some experts to advocate that a summary of momentary moods may be most appropriate for characterizing mood over longer periods of time.

Stability of Negative Affect

A fourth issue concerns the stability of negative affect over time, an issue related to the prior two points. A distinction has been drawn in the literature between state negative affect, which refers to transient fluctuations in negative emotions, and trait negative affect, which refers to enduring and stable levels of negative affect over extended periods of time. Trait negative affect, also known as negative affectivity and neuroticism, is associated with trait anxiety, poor self-esteem, introspective and ruminative behaviors, and negative views of the world and others. Important to the conceptualization of negative affect, recent studies have revealed that state negative affect and negative affectivity have differential influences on health. A study by Cohen and colleagues, for example, measured the impact of negative affect on symptoms of respiratory viral infection. Levels of state and trait negative affect were both associated with amount of subjective health complaints; however, only state negative affect was predictive of objective measures of illness (i.e., mucus weight). This study highlights the need to consider the stability of negative affect in conceptualizations of mood. As discussed below, decisions made about the stability of negative affect influence its measurement.

Measurement

There are numerous methods for measuring negative affect and mood. Among the single-item self-report measures of negative affect available, the use of a simple 0 to 7 point scale has often been used. The ends of such scales are often marked with not at all and extremely, and people simply rate where their current mood (state) and/or their general mood (trait) falls along the continuum. This measurement strategy has been used by proponents of both the specific affect and dimensional approach. Other single-item scales include bipolar scales marked with adjectives such as happy at one end of the scale and sad at the other end, and graphical approaches that use adjective labeled grids and circles based on a circumplex model of emotion. While single-item measures are available, by far the most commonly used approach to the self-report measurement of mood is the multi-item adjective checklist. This type of scale presents a participant with a number of adjectives

that are selected to represent either the specific or dimensional approach to mood. Each adjective is rated by the participants as to how well it represents either their current mood (state) or typical mood (trait). Linear combinations of adjectives are created (usually a simple summation of responses to selected groups of adjectives representing scales or dimensions) that index the level of mood. The psychometric properties (reliability, validity) of these questionnaires are excellent, and participants and patients have little difficulty completing them.

Examples of well-established mood-adjective checklists include the Nowlis Mood Adjective Checklist, which has a brief, 36-adjective version; the Profile of Mood States, which is composed of 65 adjectives and is rated for how the subjects felt over the past week; the Multiple Affect Adjective Checklist, which uses 132 adjectives to measure depression, anxiety, and hostility; and the Positive and Negative Affect Schedule, which taps the positive and negative dimensions of mood with 10 adjectives for each scale.

Observational methods for the measurement of mood are also available, although they are usually much more cumbersome and difficult to employ. Observational coding of facial expressions is a highly complex, labor-intensive, yet reliable method for measuring negative emotion. Theories of emotion involving facial feedback have been proposed, with some evidence supporting the utility of the observational measurement. While not often used in the stress literature, facial expression measurement of affect might be profitably employed in laboratory-based experiments.

In terms of negative affectivity, perhaps the most widely employed measure is the Neuroticism, Extra-version, and Openness to Experience Personality Inventory (NEO-PI). The NEO-PI is a self-report personality inventory that assesses negative affectivity and other dimensions of personality. In addition to the NEO-PI, several other measures are available that can be used to assess either state or trait negative affect, depending on the instructions given regarding the time frame of focus.

There is, then, an impressive assortment of measures for the investigator interested in measuring negative affect. Choice of an instrument for a given study will depend upon the nature of the task and the researcher's decision about the model of affect that best suits their needs.

Neighborhoods and Health
Neighborhood Stressors and Their Measurement
Evidence Linking Neighborhood Stressors and Health

Neighborhoods and Health

Neighborhoods have recently received increasing attention as relevant to health. A large body of work has documented associations of neighborhood socioeconomic characteristics (or measures of neighborhood deprivation) with a variety of health-related outcomes, including health behaviors as well as physical and mental health outcomes. For example, neighborhood disadvantage has been associated with higher prevalence of smoking, unhealthy diets, and greater incidence and prevalence of cardiovascular disease. Although the strength of the associations is often small compared to those observed for individual-level socioeconomic characteristics, they are consistent across studies and tend to persist after statistical

controls for person-level measures of social position, suggesting an independent effect of neighborhood context on health.

The extent to which associations between neighborhood socioeconomic characteristics and health reported in observational studies reflect causal mechanisms remains a subject of research and debate. An important limitation of existing work pertains to the use of neighborhood deprivation or neighborhood disadvantage as a proxy for the specific neighborhood characteristics that may be relevant to the health outcome being studied. The use of aggregate measures of neighborhood disadvantage also raises questions regarding whether residual confounding by person-level socioeconomic position could explain some of the associations observed. An important consideration in interpreting results to date is that neighborhood constructs are grossly misspecified in existing research because of its reliance on very crude proxies for neighborhoods (usually administrative areas such as wards in the UK or census tracts in the United States) and limitations in the neighborhood-level measures used. Hence, neighborhood effects are likely to be underestimated compared to the effects of individual-level variables, for which measurement strategies are much better developed.

Several specific mechanisms through which neighborhood contexts may affect health have been proposed. Some of these mechanisms involve features of the physical environment of neighborhoods and others involve features of the social environment.

The physical environment includes not only traditional physical exposures such as environmental toxins and noise, but also features of the man-made environment such as street layout, transportation availability, land use, presence and design of public spaces, and other aspects of urban design. These man-made physical features of neighborhoods have recently been referred to as the built environment. The social environment includes social norms, social cohesion, and social capital and features such as violence or social disorder. The proximate individual-level pathways through which neighborhood physical and social environments may affect individual health include health behaviors and exposures to acute and chronic stressors. For example, it has been hypothesized that street connectivity and land use mix may promote walking in daily life and physically active lifestyles. It has also been proposed that certain features of neighborhoods may serve as chronic or acute stressors with consequent physiological responses that may impair health. An important focus of current research on neighborhoods and health is to empirically examine the presence and relative importance of these different pathways and the specific neighborhood characteristics linked to them.

Neighborhood Stressors and Their Measurement

Although exposure to neighborhood sources of acute and chronic stress is often hypothesized to play a role in the relationship between neighborhood context and health, empirical documentation of the health effects of neighborhood stressors remains limited. There is still scant information of what the most relevant stress-generating features of neighborhoods might be, or on the way in which these features should be measured in empirical investigations. The most common domains investigated as potential neighborhood stressors include neighborhood problems, neighborhood disorder, violence and safety, and physical ambient characteristics.

Neighborhood problems are generally assessed by asking residents to report on the extent to which they perceive that different issues are a problem in their neighborhood. Examples of the neighborhood domains assessed include violence, noise, traffic, litter, air quality, vandalism, drug use, and presence and quality of

resources and services. Responses are typically added to construct an index of neighborhood problems. Cumulative exposure to neighborhood problems is hypothesized to be a source of chronic stress.

Neighborhood disorder refers to conditions and activities in the neighborhood that indicate a breakdown of social order. Scales to measure neighborhood disorder typically assess neighborhood markers of social incivility, disruption, and physical decay. Some researchers distinguish physical and social disorder. Signs of physical disorder include the presence of abandoned buildings, noise, graffiti, vandalism, and disrepair. Signs of social disorder include the presence of crime, loitering, public drinking or drug use, conflicts, and indifference. It is hypothesized that these signs of disorder signify a breakdown of social control and result in the experience of a threatening environment for all residents, regardless of whether they themselves have been victimized. Long-term exposure to neighborhoods with high levels of social and physical disorder is hypothesized to result in chronic stress.

Violence and perceived safety are among the most common neighborhood sources of stress investigated in empirical studies. Measures of neighborhood violence are constructed using survey responses to neighborhood violence scales or using crime statistics obtained from governmental agencies. Perceived safety is also assessed through surveys of residents. It is hypothesized that exposure to violence or to an unsafe residential environment is a source of chronic stress.

Physical ambient characteristics such as noise, crowding, housing characteristics, and proximity to environmental toxins have also been hypothesized to be sources of stress that vary across neighborhoods. These ambient characteristics are usually measured using census data or by linking residence data to other data sources, such as noise measurements or proximity to airports or environmental toxins. In contrast to neighborhood problems, neighborhood disorder, and violence/safety, which are hypothesized to affect health through psychosocial mechanisms, the factors investigated under the general rubric of physical ambient characteristics may affect health through pathophysiological mechanisms that do not involve psychological stress. For example, crowding may affect the probability of contracting infectious diseases through increased disease transmission, and environmental toxins may have direct carcinogenic or cardiovascular effects. However, it has also been argued that the perception of the presence of these physical environmental characteristics may have psychosocial consequences analogous to those observed for other stressors.

Evidence Linking Neighborhood Stressors and Health

The evidence linking neighborhood stressors to health remains limited. Most research has focused on self-reported health outcomes and health behaviors. For example, perceived neighborhood disorder has been found to be associated with poor self-reported health, poor physical functioning, adverse mental health outcomes, the presence of chronic health conditions, and heavy drinking. Although it has long been hypothesized that neighborhood sources of stress may contribute to physical health outcomes such as blood pressure, very few studies have linked neighborhood stressors to objectively measured physical health outcomes. Two physical health outcomes examined in relation to potential neighborhood stressors are blood pressure (or blood pressure reactivity) and low birth weight.

Causal inference from existing studies of neighborhood stressors and health is rendered complex by their observational design and the possibility of confounding by individual-level factors associated with place of residence. Most observational studies have only limited ability to control for these individual-level factors. Another important set of confounders includes other neighborhood attributes such as features of the built environment, which often covary with the measures of neighborhood stressors used. Measures of the physical and built environment of neighborhoods are often part of the neighborhood stressors scales used, making it difficult to determine whether it is the physical feature itself through its effects on health behaviors or the psychosocial consequence of the factor that results in the health effects. There is also little consensus on the conceptualization or the measurement of the features of neighborhoods that may be sources of stress. Thus, the extent to which neighborhood contexts affect health through the stress pathway and the relative importance of this pathway compared to pathways involving environmental influences on health behaviors or direct effects of environmental exposures (such as toxins or allergens) remain largely undetermined.

Glossary

Adrenocorticotropin (ACTH)

A 39-amino-acid peptide hormone produced from the pituitary, from a larger precursor molecule (pro-opiomelanocortin) that stimulates the secretion of glucocorticoids, mineralocorticoids, and androgenic steroids from the adrenal cortex.

Cushing's disease

The most common cause of Cushing's syndrome as a result of ACTH hypersecretion from a pituitary tumor (usually a microadenoma 3–10 mm in diameter). Chronic glucocorticoid excess that leads to skin, muscle, bone, neuropsychiatric, gonadal and metabolic abnormalities (glucose intolerance and hyperlipidemia), obesity, and hypertension.

Cushing's syndrome

Chronic glucocorticoid excess that leads to skin, muscle, bone, neuropsychiatric, gonadal and metabolic abnormalities (glucose intolerance and hyperlipidemia), obesity, and hypertension.

Gamma knife

A stereotactic radiosurgery device that allows well-defined, deep-seated brain tumors (<3 cm in diameter) to be treated in a single session under local anesthesia, using the overlapping of narrow collimated beams from 201 cobalt-60 sources.

Trans-sphenoidal surgery

Treatment of choice for pituitary tumors; the pituitary is approached from the nasal cavity through the sphenoid sinus, the anterior–inferior sella is removed, and the dura layer is incised. The adenoma is removed selectively while normal pituitary tissue is identified and preserved.

Nelson's syndrome defines patients with pituitary-dependent Cushing's syndrome (CS), i.e., Cushing's disease (CD), who have undergone bilateral adrenalectomy and have developed pituitary expansion with

increased plasma adrenocorticotropin (ACTH) levels and progressive pigmentation of the skin. Total adrenalectomy still offers the only definitive curative procedure to lower cortisol levels adequately in patients with persistent ACTH-dependent CS, in whom radiotherapy with or without medical adrenocortical enzyme-blocking therapy has been insufficient.

Pathogenesis

Plasma ACTH levels are either within the normal range or elevated modestly in patients with CD. After bilateral adrenalectomy, even during cortisol replacement therapy, plasma ACTH levels may rise as much as 20-fold, and this may be associated with tumor growth. Nelson's syndrome represents the clinical progression of a pre-existing ACTH-secreting adenoma following bilateral adrenalectomy and normalization of the hypercortisolism; the suppressive effect of excessive levels of cortisol is no longer present, ACTH secretion markedly increases, and the pituitary adenoma may thus progress. However, the exact underlying mechanism(s) leading to tumor development and excessive ACTH secretion is not well defined. Following corticotropin-releasing hormone (CRH) infusion, ACTH secretion is stimulated greater and for a longer period of time in patients with Nelson's syndrome than in those with CD. An increase in basal ACTH production and pulsatile secretion with significantly greater quantitative regularity of serial ACTH release patterns in Nelson's syndrome compared to untreated CD has been demonstrated.

Extremely high plasma ACTH levels and aggressive neoplastic growth might be explained by the lack of appropriate glucocorticoid negative feedback due to defective glucocorticoid signal transduction. At the transcriptional level, expression of pro-opiomelanocortin (POMC), the precursor molecule of ACTH, is under negative feedback control by glucocorticoids. Although mutations of the POMC promoter region that could lead to relative resistance to glucocorticoids have generally been excluded in patients with Nelson's syndrome, in one of four such tumors a mutation was found at the level of the glucocorticoid receptor, explaining the glucocorticoid resistance and probably contributing to the tumoral progression.

Incidence

Currently, bilateral adrenalectomy is rarely used to treat CD as primary surgery, with an initial cure rate of approximately 50% and an improvement rate of

around 80%. Although longer follow up after primary surgery presents an increase in recurrences, there still remain some patients with CD who will benefit from bilateral adrenalectomy. Furthermore, bilateral adrenalectomy is still used after the failure of repeated transsphenoidal surgery or pituitary radiotherapy to cure CD, in patients in whom the source of ACTH cannot be determined easily, and when the medical control of hypercortisolemia cannot be achieved adequately. Such patients are at risk of developing Nelson's syndrome, which ranges from 8% to 38% in adults, mainly in patients treated at an early age. Approximately 30% of patients develop classical Nelson's syndrome following bilateral adrenalectomy with progressive hyperpigmentation and an obvious ACTH-secreting tumor with a time interval between adrenalectomy and the diagnosis of Nelson's syndrome ranging from 0.5 to 24 years. Another 50% develop evidence of a microadenoma without marked progression, while around 20% never develop a progressive tumor. The reason for these differences in clinical behavior is not well defined and difficult to be predicted currently prior to adrenal surgery.

Pathophysiology – Molecular Pathology

Although several candidate genes that control the cell cycle, apoptosis, angiogenic, and growth factors as well as other signaling pathways have been studied, no clear information unraveling the pathophysiology of corticotroph adenomas and/or Nelson's tumors has been established. It is not yet clear whether corticotroph adenoma formation is the result of a unique molecular mechanism or a constellation of many different possibilities. However, glucocorticoids, and therefore their deprivation also, might exert variable effects on tumor growth.

Predictive Factors

Neither the duration of disease before adrenalectomy, the preadrenalectomy cortisol levels, and the suppressibility to dexamethasone administration nor the duration of postadrenalectomy follow up has been found to be an important predictor. High basal ACTH levels after adrenalectomy in excess of 600 ng l^{-1} , particularly if found less than 1 year postoperatively, were predictive of subsequent Nelson's syndrome in some, but not all, studies suggesting that no unique threshold value can be established. Although several studies have suggested that the preadrenalectomy age was the most important predictive factor for developing Nelson's syndrome, as the great majority of patients who developed Nelson's syndrome underwent an adrenalectomy before the age of 35 years,

this was not confirmed from subsequent studies. Pregnant women and children also seem to be at higher risk for the disease. Subnormal dose or noncontinuous glucocorticoid replacement therapy has also been thought to be associated with increased risk of development of the syndrome. Although a clustering of clinical, biochemical, and radiological factors can be used to try to predict the development of Nelson's syndrome there is currently no unique factor with a strong predictive value. It is hoped that a detailed molecular analysis between the slowly and rapidly growing corticotroph adenomas following adrenalectomy might provide some answers and can be used as a predictive marker.

Clinical Features

Pituitary tumors in patients with classic Nelson's syndrome are among the most aggressive and rapidly progressive tumors. All patients with Nelson's syndrome present with hyperpigmentation similar to that in Addison's disease and often an expanding intra- and/or extrasellar mass lesion. Symptoms are a consequence of extension of the tumor and compression of surrounding structures; headaches, visual field defects, and extraocular nerve palsies are among the most common clinical signs. Cases of diabetes insipidus and hypopituitarism are exceptional. Malignant transformations with central nervous system and distant metastases, as well as behavioral changes, have been described; interestingly, a number of ACTH-secreting pituitary carcinomas have developed in the context of Nelson's syndrome. Pituitary apoplexy and hydrocephalus may also complicate the course of these tumors. In addition, complications related to increased ACTH levels have been reported. Paratesticular and paraovarian tumors producing cortisol or androgens in an ACTH-dependent manner as well as testicular adrenal rests with hyperplasia have been described.

Diagnosis and Treatment

The diagnosis is suspected clinically when hyperpigmentation and signs of other mass effects on adjacent tissues develop in a patient with previous bilateral adrenalectomy and is confirmed by measuring plasma ACTH levels, which are extremely high, often ranging from 220 pmol l^{-1} (1000 ng l^{-1}) to 2200 pmol l^{-1} ($10\,000 \text{ ng l}^{-1}$). However, ACTH levels do not reflect accurately the size or aggressiveness of the tumor.

It is important to note the prevailing cortisol level when measuring ACTH, as patients with CD postadrenalectomy often have considerably elevated ACTH levels before their morning hydrocortisone

dose, whereas 1–2 h later the level may show a highly significant fall.

Thus, the diagnosis of Nelson's syndrome requires the presence of rising levels of ACTH in association with evidence of tumor growth and the presence of optimal hydrocortisone replacement therapy; pigmentation and high levels alone may simply indicate inadequate replacement therapy. The presence of tumor is confirmed by computerized tomography (CT) and magnetic resonance imaging (MRI) scans; in contrast to CD, these tumors are usually macroadenomas.

Nelson's tumors are recognized for their large size and aggressive and invasive growth. Once the diagnosis of Nelson's syndrome is made, pituitary surgery is the initial mode of treatment. Most neurosurgeons approach the tumor by the transsphenoidal route and resect as much as possible. Pituitary surgery of Nelson's macroadenomas should be performed before extrasellar expansion of the tumor occurs, as it is probably more successful when Nelson's adenomas are relatively small. Parasellar expansion, especially cavernous sinus invasion, by the pituitary tumor has been related to low surgical cure rate. Moreover, in large Nelson's tumors, spontaneous hemorrhage in the tumor can occur, which can lead to severe neurological complications. However, complete excision is not always possible and adjuvant treatment is usually required, especially if the tumor has not been irradiated previously.

The role of external beam radiation either before or postoperatively in preventing Nelson's syndrome in CD treated with bilateral adrenalectomy has not been defined clearly; adequate doses of pituitary radiotherapy, particularly immediately postoperatively, appear to decrease such an occurrence. Following the application of conventional radiotherapy, 50% of patients with Nelson's syndrome obtained normalization of plasma ACTH levels at a median of 9.5 years. However, no prospective studies comparing the incidence of Nelson's syndrome between patients who had been irradiated with either conventional or focal radiotherapy with patients who have not received such treatment are currently available.

The role of adjuvant focal beam radiotherapy in cases of patients who had previously received conventional pituitary radiotherapy, either with stereotactic multiaxial treatment (SMART) from a linear accelerator or the so-called gamma knife, is currently being investigated. A recent study failed to demonstrate any substantial response in tumor size in patients with Nelson's syndrome who received SMART.

The majority of these highly aggressive and infiltrating pituitary tumors in patients with Nelson's

syndrome frequently respond poorly to (repeated) surgical and radiotherapeutic procedures with progressive tumor growth and rising ACTH levels. An alternative approach for such patients is medical treatment to suppress ACTH hypersecretion; bromocriptine, cyproheptidine, and sodium valproate have all been used to transiently control ACTH secretion, but with minimal effect on pituitary tumor growth. Somatostatin analogs have also been used, obtaining some control of ACTH levels but not tumor size. The use of cytotoxic chemotherapy for highly aggressive tumors has also been advocated although this treatment modality is applied when no other therapeutic options are available. Recently it has been demonstrated that corticotroph adenomas express in higher density somatostatin receptor subtype 5 rather than subtype 2, which is the main target of currently available somatostatin analogs. It is believed that the newly developed somatostatin analogs that selectively bind to somatostatin receptor 5 will be more efficacious. Following recent *in vitro* data demonstrating that rosiglitazone (a peroxisomal proliferator-activated receptor (PPAR)- γ agonist) may lead to enhanced apoptosis and decreased cell division, PPAR- γ agonists show new potential for the prevention and treatment of Nelson's syndrome. Retinoids are also under investigation as it seems that they directly suppress ACTH secretion by glucocorticoid tumors.

Glossary

Gliogenesis

The generation of neuroglia; glia were recognized about 150 years ago as connective elements in the nervous system. There are three main types of glial cells in the CNS: astrocytes, oligodendrocytes, and microglia. Astrocytes and oligodendrocytes both develop from neuroepithelial cells, while microglia develop from mesodermal hemopoietic precursors. Glial cells are estimated to occupy about half the brain and outnumber neurons by about 10 to 1. Glia are involved in most aspects of neural function. Thus, during development, radial glia guide neuronal migration. Microglia are immune cells and are involved in neuroinflammation. Oligodendrocytes myelinate axons. Astrocytes play a pivotal role in the blood-brain barrier.

Lineage-specific precursors or progenitors *Multipotent progenitors*

Cells with restriction to one distinct lineage (e.g., neuronal, astroglial, glial, oligodendroglial).

Proliferative cells of the adult brain with only limited self-renewal that can

differentiate into at least two different cell lineages.

The birth of new neurons.

A generic term encompassing both stem and progenitor cells.

Neurogenesis precursor cell

Stem cells

Stem cells of the mammalian CNS are (1) self-renewing, with the theoretically unlimited ability to produce progeny indistinguishable from themselves, (2) proliferative, continuing to undergo mitosis (though perhaps with quite long cell cycles), and (3) multipotent for the different neuroectodermal lineages of the CNS, including the multitude of different neuronal and glial subtypes.

Subgranular zone (SGZ) *Subventricular zone (SVZ)*

Zone of the dentate gyrus that is the origin of stem cells in the hippocampus. Sometimes also called the subependymal zone, this zone lies immediately adjacent to the cells (ependymal) that line the walls of the lateral cerebral ventricles. In the adult, this zone gives rise to neural precursors/stem cells, the progeny of which are immature neurons that normally migrate to the olfactory bulb

Introduction

Over most of the past century of modern neuroscience, it was thought that the adult mammalian brain was incapable of generating new neurons or having neurons added to its complex circuitry. However, recent findings show that neurogenesis, the birth of new neurons, constitutively occurs in two specific regions of the adult mammalian brain (olfactory bulb and hippocampal dentate gyrus) and that there are significant numbers of multipotent neural precursors, or stem cells, in many parts of the adult mammalian brain.

The rise of precursor cell biology has brought new life to neural transplantation and the consideration of cellular replacement strategies to treat diseases of the brain. The idea of making new neurons is appealing for neurodegenerative diseases or selective neuronal loss associated with chronic neurological or psychiatric disorders. One goal of neural precursor biology is to learn from this regionally limited, constitutive neurogenesis how to manipulate neural precursors toward therapeutic neuronal or glial repopulation. Elucidation of the relevant molecular controls might allow both control over transplanted precursor cells and the development of neuronal replacement therapies based on the recruitment of endogenous cells.

This article deals with adult neurogenesis, cellular repair of the adult mammalian central nervous system (CNS), and what is known about the location, behavior, and function of precursor cells in the adult brain. In the context of CNS regeneration, this information lies at the core of all attempts to guide neuronal or glial development from neural precursors in the adult CNS for therapeutic purposes. These topics are also important for at least two other reasons. First, adult neurogenesis and precursor cell function might play an important role in the function of the healthy and diseased brain; specifically, they may underlie particular aspects of neuronal plasticity in response to functional demands. Second, neurogenesis and precursor cell biology in the adult CNS also appear to recapitulate some of the molecular, cellular, and other requirements for neuronal development in the developing brain. Neural repair is of potential importance for neurodegenerative disorders such as amyotrophic lateral sclerosis (ALS), Parkinson's disease, and Huntington's disease, as well as acquired damage such as with spinal cord injury and stress-induced neurodegeneration.

Definitions: Neural Stem Cells, Progenitors, and Precursors

Rigorously defined, adult CNS stem cells exhibit three cardinal features: (1) they are self-renewing, with the theoretically unlimited ability to produce progeny indistinguishable from themselves; (2) they are proliferative, continuing to undergo mitosis (though perhaps with quite long cell cycles); and (3) they are multipotent for the different neuroectodermal lineages of the CNS, including the multitude of different neuronal and glial subtypes. Multipotent progenitors of the adult brain are proliferative cells with only limited self-renewal that can differentiate into at least two different cell lineages (multipotency). Lineage-specific precursors or progenitors are cells with restriction to one distinct lineage (e.g., neuronal, astroglial, glial, oligodendroglial). Together, CNS stem cells and all precursor/progenitor types are, broadly defined, precursors. It is preferred to use the term stem cell as rigorously defined previously, and to use precursor or progenitor for most forms of multipotent or lineage-restricted mitotic cells. This article uses precursor cell as a generic term encompassing both stem and progenitor cells.

Adult neurogenesis comprises the entire set of events of neuronal development, beginning with the division of a precursor cell and ending with the presence and survival of a mature, integrated, functioning new neuron. Neurogenesis is sometimes incorrectly used only in the sense of precursor cell proliferation,

but this definition clearly falls short. Precursor cell proliferation is not predictive of net neurogenesis. True neuronal integration depends on many complex variables and progressive events.

Even in the absence of a fully detailed molecular characterization, neural precursor cells of the adult brain clearly possess features that justify a view of these cells as extremely promising for the goals of CNS cellular repair. They are undifferentiated, often highly mobile cells, relatively resistant to hypoxia and other injury, proliferatively active, and able to produce mature neurons and glia. The most critical caveat, however, is that precursor cells in the adult mammalian brain are heterogeneous, and, while all of these criteria might apply in many cases, it is not clear how many of the sometimes site-specific and condition-specific observations in neural precursor biology can be broadly generalized, and how many reflect particulars of a certain brain region or a certain condition.

While the identity of true CNS stem cells is as yet unknown, the heterogeneity of neural precursor cells is also an important aspect of the promise of such cells. Their variable specialization and differentiation competence provides great promise for application in medicine. The idea that one cell fits all might turn out to be as unrealistic as it is unnecessary. Adult neural precursors with partial fate restriction may, in some cases, allow for more efficient production of desired cell types. The brain itself may provide the environmental determinants for the different forms and sequelae of adult neurogenesis and gliogenesis and may powerfully enable and direct specific lineage development.

Functional Adult Neurogenesis Occurs in Nonmammalian Vertebrates

Adult neurogenesis occurs in many nonmammalian vertebrates. The medial cerebral cortex of lizards, which resembles the mammalian dentate gyrus, undergoes postnatal neurogenesis and can regenerate in response to injury. Newts can regenerate their tails, limbs, jaws, and ocular tissues and the neurons that occupy these regions. Goldfish undergo retinal neurogenesis throughout life and, impressively, can regenerate surgically excised portions of their retina in adulthood. Although some nonmammalian animals can undergo quite dramatic regeneration of neural tissue, it is unclear how relevant this phenomenon is to mammals. Indeed, it has been proposed that selective evolutionary pressures have led mammals to lose such abilities.

Birds, whose brains are much closer to mammals in complexity, also undergo postnatal neurogenesis.

Lesioned postnatal avian retina undergoes some neurogenesis, with the new neurons most likely arising from Müller glia. In songbirds, new neurons are constantly added to the high vocal center, a portion of the brain necessary for the production of learned song, as well as to specific regions elsewhere in the brain (but not all neuronal populations). It is possible to manipulate experimentally the extent to which new neurons are produced in at least one songbird, the zebra finch, which does not normally seasonally replace high vocal center (HVC-RA) projection neurons in the song production network. Inducing cell death of HVC-RA neurons in zebra finches leads to deterioration in song. Neurogenesis increases following induced cell death, and birds variably recover their ability to produce song coincident with the formation of new projections from area HVC to area RA, suggesting that induced neuronal replacement can restore a learned behavior.

The Discovery of Constitutive Adult Mammalian Neurogenesis

Ramon y Cajal (1928, p. 750) has been widely quoted as writing that “in the adult centers the nerve paths are something fixed, ended and immutable. Everything may die, nothing may be regenerated.” The relative lack of recovery from CNS injury and neurodegenerative disease and the relatively subtle and extremely limited distribution of neurogenesis in the adult mammalian brain resulted in the entire field reaching the conclusion that neurogenesis does not occur in the adult mammalian brain. Joseph Altman was the first to use techniques sensitive enough to detect the ongoing cell division that occurs in adult brain. Using tritiated thymidine as a mitotic label, he published evidence that neurogenesis constitutively occurs in the hippocampus and olfactory bulb of the adult mammalian brain. These results were later replicated using tritiated thymidine labeling followed by electron microscopy. However, the absence of neuron-specific immunocytochemical markers at the time resulted in identification of putatively newborn neurons being made based on purely morphological criteria. These limitations led to a widespread lack of acceptance of these results and made research in the field difficult.

The field of adult neurogenesis was rekindled in 1992, when it was shown that precursor cells isolated from the forebrain can differentiate into neurons *in vitro*. These results, and technical advances such as the development of immunocytochemical reagents that could more easily and accurately identify the phenotype of various neural cells, led to an explosion of research in the field. Normally occurring neurogenesis

in the subventricular zone (SVZ)/olfactory bulb and the dentate gyrus subregion of the hippocampus have now been well characterized in the adult mammalian brain.

The Location of Neural Precursor Cells and Their Isolation *in Vitro*

If adult multipotent precursors were limited to the two neurogenic regions of the brain, the SVZ and dentate gyrus, it would severely limit the potential for neuronal replacement therapies based on *in situ* manipulation of endogenous precursors (Figure 1). However, *ex vivo* studies, in which precursors were isolated from the adult brain, provide evidence for cells with precursor cell properties in the adult brain. Such cells were first found embryonically, then in the adult hippocampus and the SVZ. Following these first reports, cells with similar properties have been isolated from many other adult mammalian brain regions as well. Neural precursor cells can be propagated in two main forms: in adherent cultures and under floating conditions, in which they aggregate to form heterogeneous ball-like structures, termed neurospheres. While it has become standard for some groups to use this so-called neurosphere-forming assay as a key criterion for neural stem cells, the ability to form a neurosphere, alone, is not a sufficiently reliable hallmark of stem cells and does not fully differentiate between various mitotic and precursor cell populations. Clonal analysis provides important additional information. By subcloning individual cells, one can test whether an individual cell from these spheres can again give rise to secondary spheres, which upon transfer into differentiation conditions can produce all neural lineages (see Figure 1).

In vitro, many such factors are likely to be present in the complex media used to culture neural precursors. Epidermal growth factor (EGF) and fibroblast growth factor 2 (FGF-2) are two key growth factors used in neural precursor cultures to maintain cells in their mitotic and undifferentiated state. The general effectiveness of both factors as mitogens for precursors has also been demonstrated *in vivo*, and they have been used more recently to enhance induced neurogenesis in the normally nonneurogenic CA1 region of the hippocampus after focal ischemia. However, their effects *in vivo* are not identical to those *in vitro*, and, consequently, their physiological relevance for normal neural precursor cell function of the adult brain is not known.

The efficacy of an individual growth factor *in vitro* does not prove that it plays a role in neurogenic permissiveness *in vivo*. Cell culture systems are highly artificial in many respects. *In vivo*, precursor cells

Figure 1 From Emsley, J. G., et al. (2005). *Progress in Neurobiology* 75, 321–341.

are never alone. Their relationship to a neurogenic microenvironment might be inseparable from their inherent properties. Regional differences *in vivo* reinforce the importance of the microenvironment for normal precursor cell function and neurogenesis. Nevertheless, *in vitro* studies are indispensable for many questions in neural precursor biology, including investigation of the transcriptional control of adult neurogenesis and neural differentiation.

Neurogenic versus Nonneurogenic Regions in the Adult Brain

In the adult mammalian brain, constitutive neurogenesis occurs only in the olfactory bulb and the dentate gyrus of the hippocampus. In the olfactory system, precursor cells reside in the anterior aspect of the SVZ in the walls of the lateral ventricles, migrate into the olfactory bulb, and differentiate into granule or periglomerular interneurons. In the dentate gyrus of the hippocampus, the precursor cell population is found in the subgranular zone (SGZ) of the dentate gyrus. Here, new hippocampal granule cell neurons are produced. These two brain regions are thus referred to as neurogenic regions of the brain. As is discussed in more detail later, reports of low-level and transient constitutive neurogenesis in the normal neocortex have been disputed, primarily for methodological reasons. Single reports have also appeared on constitutive adult neurogenesis in the amygdala, area CA1 of the hippocampus, the dorsal vagal complex of the adult brain stem, the spinal cord, and the substantia

nigra, although some of these results have been disputed and require further investigation.

Transplantation studies support the principle of defining neurogenic and nonneurogenic regions and provide evidence about the role of the microenvironment in influencing the potential of neural precursors. If precursor cells are transplanted into neurogenic regions, they can differentiate into neurons in a region-specific way. SVZ precursor cells generate hippocampal neurons when transplanted into the hippocampus, and SGZ precursor cells generate olfactory interneurons after transplantation into the rostral migratory stream of the olfactory ventricle (anterior extension of the lateral ventricle). When implanted outside the neurogenic regions, both types of precursor cells generate only glia. These data further support the interpretation that neurogenesis is dependent upon a permissive microenvironment, rather than on the regionally different properties of precursor cells. Local microenvironmental influences on the behavior of precursors and their ability to differentiate into neurons support the argument that it will be critical for the goal of neuronal repopulation to understand the cellular and molecular controls over cell type-specific precursor cell differentiation in the adult CNS.

It came as a surprise to many in the field that neurogenic regions are defined by the neurogenic permissiveness of the local microenvironment, rather than by the presence of neural precursor cells. Neural precursor cells have been found in a large number of brain regions, including white matter tracts. It is

possible that the entire brain contains neural precursor cells (albeit at very low density), just as it contains partially restricted glial precursors that act as progenitor cells. These widely distributed neural precursor cells do not seem to differ fundamentally from one another, although they are far from homogenous, with notably different growth kinetics and differentiation potential. Their function outside the classical neurogenic regions is not known, nor is their relation to the precursor cells of the neurogenic regions. For example, neural precursor cells from the spinal cord behave *in vitro* much like their counterparts from the SGZ and SVZ. That is, they are multipotent after implantation into the hippocampus, producing granule cell neurons, but generate only glial cells and no neurons *in situ* or when transplanted back to their original site in the spinal cord. *In vivo*, no adult neurogenesis can be found in the rodent spinal cord. In sum, the extent of neurogenesis in a region is a function of the local microenvironment on precursor cells with (varying) neurogenic potential.

There is, therefore, an important conceptual distinction between neurogenic and nonneurogenic regions, which might reflect complex molecular and functional states rather than a fixed cellular environment. Can nonneurogenic regions be molecularly modified to promote neurogenesis? Could this change in neurogenic permissiveness be induced under certain pathological conditions? There are strong natural precedents in other vertebrate systems, such as the avian telencephalon and the olfactory epithelium, for the concept that selective neuronal death can alter the differentiation of precursors, thereby inducing or increasing neurogenesis. While not yet proven, it is hypothesized that this change in neurogenesis occurs via alterations in the local molecular microenvironment that resemble conditions seen during nervous system development and in adult neurogenic regions.

Factors That Stimulate Neurogenesis

Seizure Activity

Seizure activity can increase hippocampal neurogenesis. However, it appears that seizure-induced neurogenesis may contribute to inappropriate plasticity, highlighting the fact that newly introduced neurons need to be appropriately integrated into the brain in order to have beneficial effects. Chemically or electrically induced seizures induce the proliferation of SGZ precursors, the majority of which differentiate into neurons in the granule cell layer. However, some newborn cells differentiate into granule cell neurons in ectopic locations in the hilus or molecular layers of the hippocampus and form aberrant connections to

the inner molecular layer of the dentate gyrus, in addition to the CA3 pyramidal cell region. It is hypothesized that these ectopic cells, with their aberrant connections, might contribute to the phenomenon of hippocampal kindling.

Behavioral Environment

Events occurring in the hippocampus dramatically demonstrate that behavior and environment can have a direct influence on the brain's microcircuitry. Animals living in an enriched environment containing toys and social stimulation have more newborn cells in their hippocampus than control mice living in standard cages. Experiments to further assess which aspects of the enriched environment contribute to increased neurogenesis revealed that part of the increase can be attributed simply to exercise via running. Associative learning tasks that involve the hippocampus also appear to increase neurogenesis. While this is still quite speculative, it is possible that the processes mediating these effects on neurogenesis may underlie some of the benefits that physical and social therapies provide for patients with stroke and brain injury. IGF-I appears to be one of the factors that might mediate behavioral influences on hippocampal neurogenesis.

Stress and Neurotransmitter Effects

Stress increases systemic adrenal corticosteroid levels and reduces hippocampal neurogenesis. Conversely, adrenalectomy, which virtually abolishes adrenal corticosteroids, increases hippocampal neurogenesis, suggesting that adrenal hormones at least partially mediate the effects of stress on hippocampal neurogenesis. Serotonin is a strong positive regulator of adult hippocampal neurogenesis. Drugs that increase serotonin action, such as antidepressants, increase neurogenesis. Together, these results demonstrate that adult neurogenesis can be modified by systemic signals, suggesting that modifying such systemic signals in addition to local signals may be useful in developing potential future neuronal replacement therapies involving manipulation of endogenous precursors.

Transcription Factors and Signaling Pathway Effects

Transcription factors and chromatin proteins, such as the methyl-CpG binding protein and HMGB1 chromatin protein, may regulate adult hippocampal neurogenesis, and Wnt signaling might also play a critical role in controlling the fate of hippocampal neural stem cells. The developmentally critical basic helix-loop-helix (bHLH) transcription factor *NeuroD* has

also been shown to be involved in adult hippocampal neurogenesis.

Depression and Neurogenesis

An interesting, but quite speculative and controversial, hypothesis concerning the role of hippocampal neurogenesis in human depression has been proposed and is outlined later in the article.

Induction of Neurogenesis in Nonneurogenic Regions of the Adult Brain

Induced neurogenesis in nonneurogenic regions can be envisioned in two basic forms: (1) local parenchymal precursor cells might be activated to generate new neurons upon a stimulus associated with a pathological event or with a set of directed molecular and/or genetic signals, or (2) precursor cells from normally neurogenic regions (e.g., the SVZ) might respond to either type of stimulus and migrate into the parenchyma. There are examples for both possibilities.

Several groups have recently demonstrated the induction of modest levels of neurogenesis in normally nonneurogenic regions in response to selective neuronal death or degeneration. As described later, Magavi et al. found that endogenous multipotent precursors normally located in the adult brain can be induced to differentiate into neurons in the normally nonneurogenic adult mammalian neocortex, a result recently extended to corticospinal motor neurons. More recently, other groups have reported similar and complementary results in a normally nonneurogenic region of the hippocampus and in the striatum, confirming and further supporting this direction of research. These reports of seemingly regenerative neurogenesis in the vicinity of targeted cortical neuron degeneration and cerebral ischemia suggest that the lack of normal neurogenic permissiveness in these regions is not unalterable. The controversial examples of reportedly extremely low-level constitutive neurogenesis outside the classical neurogenic regions might also support this possibility, potentially as leakage from normally tightly inhibited systems. Are precursor cells resident in nonneurogenic regions waiting for either instructive neurogenic signals or release from inhibition to awaken them to develop into new, function-restoring neurons?

Magavi et al in 2000 were the first to show that regenerative neurogenesis is possible in the neocortex. Induced synchronous apoptotic degeneration of corticothalamic neurons of layer VI of anterior cortex in adult mice led to the generation of new nerve cells in this region that projected to the thalamus. This work served as a proof of concept for the induction of adult mammalian neurogenesis in cortex

that has been extended to the striatum, hippocampus, and corticospinal system (see below). Thus, although the density of multipotent precursors in adult brain outside the anterior SVZ and the dentate gyrus is exceedingly low, these precursors under an appropriate *in vivo* environment (such as that generated by apoptotic neurons) can differentiate into astroglia, oligodendroglia, and neurons: the latter can receive afferents and extend axons to their appropriate targets. That is, cerebral cortex undergoing targeted apoptotic degeneration can direct multipotent precursors to integrate into adult cortical microcircuitry. The population specificity of neuronal death was found to be essential, allowing for maintenance of local circuitry and survival of surrounding cells that alter gene expression to direct precursors. Other groups have reported similar and complementary results in hippocampus and striatum, confirming and further supporting this direction of research. Nakatomi and colleagues, using an *in vivo* ischemia model, found that repopulation of neurons in the CA1 region of the hippocampus is possible following the elimination of CA1 neurons. Recently, Chen et al. demonstrated induction of low-level neurogenesis of corticospinal motor neurons, with progressive extension of axons into the cervical spinal cord over 3 to 4 months. The critical challenge will be to assess true functional integration of recruited adult-born neurons.

Taken together, these results demonstrate that endogenous neural precursors can be induced to differentiate into CNS neurons in a region-specific manner and at least partially replace neuronal populations that do not normally undergo neurogenesis. It appears that these results may be generalized to at least several classes of projection neurons, including the clinically relevant striatal medium spiny neurons and corticospinal motor neurons. Microenvironmental factors appear capable of supporting and instructing the neuronal differentiation and axon extension of adult-born neurons derived from endogenous precursors.

Function of Adult Neurogenesis and Neural Precursor Cells in the Adult Brain

Given the restricted regional occurrence of constitutive neurogenesis in the adult mammalian brain, it is reasonable to hypothesize that there are specific contributions of adult neurogenesis to the functions of the hippocampus and the olfactory system. Possibly, these functions differ fundamentally from functions found elsewhere in the brain.

For the most part, the adult brain seems to do just fine without the ability to generate or regenerate

neurons. Obviously, this characteristic of the mammalian CNS presents as a disadvantage in cases of neuronal loss, which cannot be replaced, but one theory is that this is the price paid during evolution for increasingly powerful and complex computing power. This reasoning posits that the cardinal requirement for stability in the system precludes the capability for neuronal replacement. Despite its appeal and clarity, this theory has for years been at odds with the fact that, even without considering actual cellular replacement or addition via neurogenesis, there is amazing structural and synaptic plasticity in the brain. Nonetheless, the fact remains that there is normally no (or extremely little) neurogenesis outside the two specific neurogenic regions of the adult brain. This striking restriction of neurogenesis to these two regions suggests that the question should be asked differently: What are the special functions of the dentate gyrus and olfactory bulb that require maintenance adult neurogenesis?

In simple terms, the hippocampus and olfactory system would appear to have little in common functionally. Whereas the hippocampus is one of the best-studied areas of the brain and has been named the gateway to memory because of its important and indispensable role in learning and memory, much less is known about the olfactory system. However, considering the evolutionary importance of olfactory perceptual learning, and the similar output modulatory roles of dentate gyrus granule neurons and olfactory bulb granule neurons that have been postulated, the functions of neurogenesis in each system might indeed be more closely related.

A gatekeeper theory has been proposed to help explain the potential function of adult-born dentate gyrus granule neurons. This theory hypothesizes that new granule cells allow for optimization of the mossy fiber connections between the dentate gyrus and CA3 in accordance with the level of complexity and novelty frequently encountered by an individual. Because adult neurogenesis occurs at a bottleneck connection, even a few new neurons could have a large impact. Selectively eliminating the adult-born neurons would be the method of choice to test this idea. However, both irradiation and treatments with cytostatic drugs as a means of killing dividing precursor cells are less selective than would be desired, with many structural and potentially functional side effects. Therefore, despite being highly intriguing, results of such studies have remained ambiguous and difficult to interpret.

Similarly, while the precise function of new neurons in the olfactory bulb is not yet known, recent evidence from Magavi, Macklis, and colleagues has identified an entirely novel function of adult-born olfactory

bulb granule neurons – they are especially responsive to novel odorants and undergo experience-dependent modification in response to familiarization with novel odorants presented as the neurons are integrating into functional circuitry. Selective circuit integration of activated neurons might underlie at least some of this change in population response. These results indicate that adult-born granule neurons provide a novel form of synaptic plasticity via insertion of entirely new cellular units into existing functional circuitry.

Consequences of Disturbed Adult Neurogenesis and the Reaction of Neurogenic Regions to Disease

Because so little is known about the physiological function of adult neurogenesis, it has been difficult to evaluate the possible consequences of disturbed neurogenesis. Nevertheless, altered adult hippocampal neurogenesis has been proposed to play a role in a number of disorders. The most robust data that support this role come from studies of temporal lobe epilepsy.

Experimental seizures are a robust inducer of cell proliferation and net neurogenesis. Because of this, dysregulated adult neurogenesis might provide an explanation for the development of the granule cell dispersion found in many cases of temporal lobe epilepsy. There is some evidence that ectopic neurons can form in seizure-induced neurogenesis and that they might contribute to seizure activity. In addition, there have been recent reports of increased neurogenesis in Alzheimer's disease, as well as in Huntington's disease. Further, experimental depletion of dopamine in a rodent model of Parkinson's disease has been reported to decrease precursor cell proliferation in both the SVZ and dentate gyrus. The reproducibility and functional significance of these phenomena in neurological disorders have yet to be evaluated.

Several experimental data suggest another quite speculative hypothesis, that a failure of adult hippocampal neurogenesis might underlie major depression. Patients with long-lasting depression have global hippocampal atrophy. Consistent with this hypothesis, stress-related glucocorticoids are associated with a decrease in neurogenesis, and increased serotonin levels are associated with an increase in neurogenesis. If adult neurogenesis is blocked by irradiation, the behavioral effects of fluoxetine treatment (a serotonin reuptake inhibitor) have been found to be abolished. However, the hippocampus is generally thought to be involved in memory consolidation and less involved in the generation of mood, suggesting that altered hippocampal neurogenesis may be secondary

to, rather than causative of, depression. Further, depression is not thought to be primarily a hippocampal disorder, and the presumed link to adult neurogenesis would need to depend strongly on the functional contribution of new dentate gyrus neurons to hippocampal function. The fact that neurogenesis occurs only in the dentate gyrus, while hippocampal atrophy in depression and positive effects of therapies are widespread throughout the hippocampus, argues that these phenomena are not directly linked. Thus a possible link between depression and neurogenesis remains speculative and in need of further rigorous analysis.

Conclusions and Future Prospects

Neurogenesis and neural precursor/stem cell biology suggest that the generation, insertion, and functional integration of new neurons is possible in the adult mammalian brain. From the point of view of fundamental neuroscience, it is important to learn about the normal role of precursor cells and the normal function of neurogenesis in the neurogenic regions of the adult CNS. This information might have immense implications for our understanding of brain function in development, normal adulthood, and disease states. Circuit plasticity at the level of individual cells, neuronal or glial, adds a new layer of complexity to our understanding of how brain structure and function interact. Better understanding of these issues may enable the prevention of disease and dysfunction, beyond the established goals of trying to repair neurons lost as a consequence of neurodegeneration and CNS damage. A better understanding of the cellular and molecular controls over differentiation of neural precursor cells along specific cellular lineages during development and in the adult CNS will be critical for the development of cellular therapeutic approaches for repopulating damaged or diseased areas of the nervous system. The future prospect of directing the development and integration of precursors in the adult mammalian brain toward the replacement of lost neurons or glia is exciting, and several recent lines of work provide remarkable progress toward this aim.

Overview of Neurodegenerative Disorders

Neurodegenerative Dementias: Alzheimer's Disease

Neurodegenerative Movement Disorders: Parkinson's Disease

Conclusions

Glossary

<i>Alzheimer's disease</i>	A progressive neurodegenerative dementia affecting memory and other cognitive functions.
<i>Hippocampus</i>	Area of the brain concerned with encoding and storage of new declarative memory.
<i>Neuron</i>	Single cell functional unit of the nervous system.
<i>Parkinson's disease</i>	Progressive neurodegenerative disorder affecting movement, balance, and postural stability.
<i>Substantia nigra</i>	Area of the brain principally affected in Parkinson's disease containing a high concentration of dopaminergic neurons.

Overview of Neurodegenerative Disorders

Neurodegenerative disorders are characterized by a gradual loss of neurons, often leading to death. The term encompasses a broad range of clinical diseases, including progressive dementing conditions, of which the most common are Alzheimer's disease (AD), movement disorders, exemplified by Parkinson's disease (PD), and a range of other neurological disorders. Neurodegenerative disorders have in common a

gradual loss of neurons and synaptic connections, usually occurring in later life. Specific diseases are distinguished by the presence of characteristic symptoms that depend on the location at which neuronal loss is occurring in the brain. Typically, the degree of neuronal loss correlates directly with the appearance and progression of the clinical symptoms. In AD, neuronal loss occurs early in the hippocampus, a brain region concerned with declarative episodic memory. In PD, the characteristic clinical triad of tremor, bradykinesia, and postural instability only become evident after 70–80% of dopaminergic neurons in the substantia nigra are lost.

The gradually progressive nature of these disorders, often combined with a long preclinical course before the development of symptoms, allows ample time and opportunity for environmental factors such as stress to contribute to disease development and progression. These features, however, make detection of environmental factors with disease-modifying effects by traditional epidemiological methods difficult. Prospective studies attempting to identify associations between stress beginning early in life and a clinical syndrome many years later in middle or even late life are hindered by the long length of time between exposure and disease onset, while retrospective studies are hampered by trying to quantitate environmental stress and account for the large fluctuations that occur over the course of a lifetime. Additionally, definitive diagnosis of most neurodegenerative disorders requires inspection of brain pathology after death, further complicating study of patients during life. Consequently, most knowledge concerning the relationship of stress to neurodegenerative disorders originates either from studies of animal models or from changes in stress-related hormones in those with neurodegenerative disorders compared to those without.

Despite the limitations, the scientific literature substantially supports an association of psychological

and physiological stress with the risk of neurodegenerative disease. This article describes the clinical and neuropathological findings of AD and PD, as illustrative of the most common neurodegenerative disorders. It describes the effects of stress on animal models of neurodegenerative disorders and evidence for alterations in stress hormones in the setting of neurodegenerative disease.

Neurodegenerative Dementias: Alzheimer's Disease

AD is the most common neurodegenerative disorder and a major health-care problem that will continue to increase in importance as the U.S. population ages. Currently, more than 4 million Americans have a diagnosis of AD, resulting in enormous economic and social costs for their care, with a total in the United States alone approaching \$100 billion per year.

AD occurs primarily but not exclusively in the elderly, with onset in most patients occurring after age 65. More rarely, onset may occur as early as the fourth decade of life, particularly in those with a familial form of the disease. Overall, prevalence for AD among the elderly (age 65 or greater) is about 6%, doubling approximately every 5 years after age 60, affecting between 26 and 45% of those age 85 or older. The annual incidence of new cases of AD per 100 000 people in the United States also rises with advancing age, one reason why investigators predict that AD will affect an increasingly large number of persons in the coming years, as the average age of the U.S. population increases. Some have predicted that in the United States the number of people with this disease may reach 14 million by the year 2050.

In the absence of a definitive clinical test or biomarker, the clinical diagnosis of AD depends on clinical criteria. The diagnosis of clinically probable AD by National Institute of Neurologic and Communicative Disorders and Stroke and the AD and Related Disorders Association Work Group (NINCDS-ADRDA) criteria requires impairment in at least two cognitive domains, progressive deterioration, absence of delirium, onset between 40 and 90 years of age, and lack of evidence for other dementing diseases after a standard work-up. Besides memory, other cognitive domains that may be affected include language, visuospatial perception or constructions, calculations, praxis, and executive functions. Patients meeting these criteria typically display progressive impairment in activities of daily living such as driving, buying groceries, preparing meals, doing laundry, and basic functions such as walking safely and maintaining personal hygiene. The diagnosis of clinically probable AD using NINCDS-ADRDA

criteria reportedly results in correct identification at autopsy in 85 in 95% of cases. Like other neurodegenerative disorders, gradual deterioration until death is typical, with a mean survival after symptom onset of 10.3 years.

The definitive diagnosis of AD requires clinico-pathological correlation. One hallmark of the disorder is the presence of intracellular neurofibrillary tangles (NFTs) containing the microtubule associated tau protein in an abnormal phosphorylated state. Another hallmark of AD is the presence of extracellular senile or neuritic plaques greater than expected for the patient's age. The central core of these plaques is composed of β -amyloid peptides such as A β 42. Around this amyloid core are degenerating dendrites and axons, some of which contain paired helical filaments like those found in NFTs. In addition to NFTs and neuritic plaques, the neuropathology of AD, like all neurodegenerative disorders, includes a progressive loss of neurons and their synaptic connections.

Both familial and environmental risk factors exist for development of AD. First, the development of AD at an early age (younger than age 65) often occurs as a result of autosomally dominantly inherited mutations in genes such as presenilin 1 and 2 and the amyloid precursor protein. Second, presence of an apolipoprotein E genotype with at least one ϵ 4 allele results in an earlier age of onset of the disorder. Apolipoproteins are cholesterol-bearing proteins that mediate neuronal protection and repair and may participate in A β 42 deposition. Third, women appear to be at slightly greater risk for AD, even when accounting for their greater longevity over men. Fourth, in addition to age, risk for AD increases with traumatic head injury, small head size, and low education, presumably on the basis of decreased neuronal reserve. Finally, later age of symptom onset, prominent psychiatric symptoms, and comorbidity such as cerebrovascular disease, heart failure, a history of heavy alcohol use, excessive weight loss, and institutionalization all may have a negative impact on clinical progression and eventually survival. In contrast, environmental and familial risk factors such as ethnic background and marital status are not proven to affect survival or rate of disease progression.

More recent evidence implicates psychological stress as an additional risk factor for the development of AD. Several studies show that patients with a high susceptibility to distress are more prone to AD in later life. When patients are followed to autopsy, those with a high susceptibility to distress as indicated by the personality trait of neuroticism are twice as likely as those without this susceptibility to have the NFTs and neuritic plaques of AD. Those with high distress proneness have a greater than 10-fold increase in

episodic memory decline compared to those with low distress proneness. Other studies indicate that everyday hassles and challenging life events may exacerbate age-related declines on episodic memory tests. These findings implicate accelerated damage to the hippocampi as the mediator of the effects of stress on memory.

Much data indicate that the hippocampal region is involved in the response to stress. Animal and human studies indicate memory deficits associated with hippocampal damage after chronic stressful experiences. Corticosteroid receptors are abundant in the hippocampus, and high, stress-induced concentrations of glucocorticoids become toxic to the hippocampal neurons. Studies have reported high concentrations of cortisol in association with hippocampal atrophy in patients with dementia, as well as in posttraumatic stress disorder and major depression.

Many studies suggest abnormal function of the hypothalamic-pituitary-adrenal (HPA) axis in patients with AD. There are reports of increased serum cortisol levels and reduced feedback inhibition of cortisol secretion in patients with AD. Corticosteroid hypersecretion may downregulate the hippocampal corticosteroid receptors, which in turn dampens the feedback inhibition of the HPA, leading to further hypersecretion and eventual hippocampal neuronal loss. Other studies have focused on abnormal neuroendocrine responses to challenge with a chemical agent. Several studies report that AD patients demonstrate elevated cortisol levels relative to nondemented controls after challenge by a dexamethasone suppression test. In these studies, cortisol levels after administration of dexamethasone correlated directly with dementia severity. Another study compared cortisol and prolactin responses to administration of naltrexone, an opiate antagonist, in AD patients and normal elderly controls. In this study, normal control patients demonstrated a significantly greater increase in cortisol levels after a single dose of naltrexone compared to the AD patients, with no difference in prolactin response between the groups. Finally, cortisol levels have been shown to directly correlate with severity of cognitive decline and degree of hippocampal atrophy in AD patients.

One further mechanism for stress-induced injury in AD is vascular. The neuropathology of AD and the cerebrovascular changes may be synergistic. Higher stress-induced systolic and diastolic blood pressure (BP) reactivity, including variability in BP on 24-h ambulatory monitoring, has been associated with decreased performance in verbal memory and executive tests. The relation of BP reactivity to decreased cognitive function may be mediated by

silent cerebrovascular changes from cerebral hypoperfusion. Repeated episodes of stress-induced BP reactivity can result in white matter changes or other silent cerebrovascular lesions on neuroimaging. Finally, life may also produce a hypercoagulable state that could contribute to cerebrovascular disease.

Neurodegenerative Movement Disorders: Parkinson's Disease

PD is an extrapyramidal movement disorder of unknown etiology, with onset between the ages of 50 and 65 years, and is more common in males than females with a ratio of 3:2. PD is fairly common, with a prevalence of approximately 100 to 180 per 100 000 population. Disease course is shorter on average than AD, with an 8-year mean duration of illness. Patients with PD have a two- to fivefold increased mortality compared to nondemented people in the same community. Risk of mortality directly relates to symptom severity, with death typically occurring due to aspiration pneumonia, urinary tract infection, or unrelated conditions of the elderly.

Clinically, PD has five primary characteristics: resting tremors, rigidity, bradykinesia, postural instability, and responsiveness to treatment with dopaminergic agents. In any particular patient some components may be evident and others not, and components are commonly asymmetric at onset. Of the primary clinical characteristics, presence of tremor is most suggestive of PD as opposed to other parkinsonian disorders. The tremor is classically present at rest, occurring at approximately four to eight cycles per second, and may develop in one upper extremity before spreading to involve all four limbs, face, and tongue. Bradykinesia contributes to the expressionless or masked face, sialorrhea, and micrographia. The gait is festinating, with abnormal righting reflexes and a slightly flexed posture. Eye movements may have subtle abnormalities in voluntary gaze, pursuit, and convergence. Many patients develop autonomic symptoms including postural hypotension, impotence, atony of the large bowel with constipation, and esophageal spasm.

Characteristic pathological changes of idiopathic PD typically occur in the pars compacta of the substantia nigra. Classically, there is marked depigmentation and neuronal loss, with presence of Lewy bodies in this region. As a consequence of these changes, dopaminergic neurons in the substantia nigra pars compacta are lost, affecting projections to the corpus striatum. Less pronounced changes are evident in a variety of other brain stem and diencephalic nuclei, including the locus ceruleus, dorsal

vagal nucleus, and sympathetic ganglia. Although depletion of dopamine is the classic neurotransmitter deficit in PD, levels of norepinephrine, glutamate decarboxylase, GABA, methionine-enkephalin cholestokinin, and serotonin are also decreased in the substantia nigra of PD patients. No evidence supporting or suggesting a link between stress and neurotransmitter levels has been reported in PD.

Lewy bodies are characteristic of PD. Certain sites show a predilection for development of Lewy bodies, including the entorhinal region, the CA2 sector of the hippocampal formation, limbic nuclei of the thalamus, anterior cingulate, agranular insular cortex, amygdale, ventromedial divisions both of the basal and accessory basal nuclei, and central nucleus. Lewy bodies are composed of aggregates of α -synuclein, suggesting a possible central role for this protein in the pathogenesis of PD. Further evidence in the form of dopaminergic loss and inclusion body formation in α -synuclein mice reinforces a causal role for α -synuclein in this disorder. The proposed pathological mechanism starts with a reduction in the solubility of α -synuclein, resulting in the formation of filaments, which then aggregate into the cytoplasmic inclusions called Lewy bodies that contribute to the dysfunction or death of the glial cells and neurons in which they form in PD patients. However, no evidence for a relationship between degree of pathological changes or presence of Lewy bodies and stress has been reported in PD.

Environmental risk factors for PD include age, family history, and rural living possibly related to pesticide exposure. A genetic component to risk for development of PD is suggested by some studies reporting an increased prevalence rate of PD in relatives of PD patients compared to the general population. This has not been confirmed in twin studies, which failed to demonstrate increased concordance among identical twin pairs. Exposure to environmental toxins may be a rare cause of PD, such as from exposures to pesticides or herbicides and well water consumption. In contrast to AD, most studies do not find that APOE e4 is a risk factor for PD or PD dementia; however, PD patients show a trend toward slightly higher APOE e4 allele frequencies (12.5 to 17%) compared to normals (10 to 12.5%). One study showed that the APOE e4 allele frequency was significantly higher for PD dementia compared to PD and may affect an earlier age of onset for PD. Additionally, while female gender is associated with an increase risk of developing AD, male gender is associated with increased risk of PD.

Stress is probably an additional risk factor for PD. When compared to levels in unaffected spouses and

siblings, cortisol levels in untreated patients with idiopathic PD are elevated. Other neuroendocrine abnormalities such as elevated levels of prolactin and decreased levels of growth hormone and adrenocorticotrophic hormone have been demonstrated in patients with PD compared to normal controls. The clinical understanding of HPA axis dysfunction in PD, however, is often complicated by medical treatment, since selegiline, a medication used in treating patients with PD, may lower cortisol levels. Investigators have studied neuroendocrine abnormalities in a dog model of PD, using 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)-treated animals. After MPTP treatment, which damages neurons in the substantia nigra, plasma ACTH and cortisol are elevated in the treated dogs compared to untreated controls. In these animals, elevated cortisol levels result in excessive stimulation of neuronal glucocorticoid receptors, contributing to excitotoxic cell death. Excitatory stimulation of postsynaptic glutamate (NMDA) receptors in nigrostriatal neurons increases intracellular concentrations of calcium, possibly leading to disruption of the cell cytoskeleton or activation of caspase pathways leading to programmed cell death. Increased oxidative stress at the cellular level is also important in the pathogenesis of PD. Oxidative stress, through the depletion of glutathione and other free radical detoxificant enzymes, impaired mitochondrial complex I activity, or enhanced iron-mediated free radical production may contribute directly to neuronal loss in PD.

Conclusions

In summary, stress and its physiological effects may play a role in the progressive loss of neurons that occurs in neurodegenerative disorders. Increased cortisol levels due to both acute and chronic stress have demonstrated associations with hippocampal degeneration and memory impairment. This may be particularly relevant in the study of neuronal loss in AD, a disorder in which hippocampal degeneration occurs early in the disease course. Stress-induced alterations in BP and consequent vascular injury may further predispose to AD. In PD, elevated cortisol levels result from abnormalities of the function of the HPA axis, possibly contributing to loss of dopaminergic neurons in the substantia nigra by a variety of mechanisms, including excitotoxic cell death, increased intracellular calcium levels, and increased oxidative stress. Much more research is vitally needed in order to more clearly characterize and understand the contributions of stress to AD, PD, and the many other neurodegenerative disorders.

Autism and Asperger's Disorder

Attention-Deficit/Hyperactivity Disorder (ADHD)

Stress Associated with Autism and ADHD

Conclusion

Glossary

Pervasive developmental disorders (PDD) A group of serious neuro-developmental disorders affecting communication and social skills and behaviour.

Autism (autistic disorder) A PDD that involves delayed and deviant language development, impaired social skills and ritualistic and repetitive

patterns of behaviour, usually associated with intellectual disability but a minority have normal IQ (high functioning).

A PDD characterised by normal intellectual ability and language development but the presence of impaired social skills and ritualistic and repetitive patterns of behaviour.

A term usually applied to represent autistic disorder, Asperger's disorder and atypical autism or PDD not otherwise specified (PDD-NOS) which share some common features of problems with communication and social skills and behaviour.

A neuro-developmental disorder presenting with inattention, impulsiveness and motor hyperactivity excessive for the developmental age and usually associated with learning problems.

Asperger's disorder

Autism spectrum disorder

Attention-deficit/hyperactivity disorder (ADHD)

Autism and Asperger's Disorder

Autistic disorder (referred to as autism here) and Asperger's disorder are classified under the umbrella term pervasive developmental disorders (PDDs). PDD applies to children who share the core features of severe and pervasive impairment in social and communication skills, together with the presence of restricted and repetitive patterns of behavior and interest. Other disorders that are categorized as PDDs include Rett's disorder, childhood disintegrative disorder, and pervasive developmental disorder, not otherwise specified (PDD-NOS). These disorders have their onset within the first 3 years of life. This section focuses on the two main PDDs, autism and Asperger's disorder. The term autistic spectrum disorders (ASDs) is frequently used to describe a group of individuals with either autism or Asperger's disorder and is used accordingly in this article.

Epidemiology

The prevalence of autism is around 10–12 per 10 000. There is no evidence that prevalence varies between countries or racial groups, and social class and level of parental education are not associated with autism. Autism is more common in boys than girls (4:1), and this gender distribution is even more marked in Asperger's disorder (10–13:1).

Clinical Features of Autism

Autism presents with delays and abnormalities in the development of language and social skills and the presence of rigid, repetitive, stereotyped play and behavior, often in association with intellectual disability (i.e., an IQ below 70) and a variety of neurological conditions such as epilepsy. A reliable diagnosis can be made from the age of 2 years. Parents usually first seek help because their child has language delay and a lack of nonverbal communication. About 50% of children with autism fail to develop functional speech and only slowly learn to compensate with gesture. Language development is often abnormal in the remainder, with echolalia, self-directed jargon, and the repetition of irrelevant phrases, for example, from a television show. The correct use of pronouns and the related development of a sense of self and others are delayed. Poor comprehension, problems expressing needs by words and gesture, and difficulty in social understanding are frequently the causes of stress, frustration, and disturbed behavior. Children who do develop functional language usually have difficulty in using language socially and in initiating or sustaining reciprocal conversations. In contrast to children with autism, young people with Asperger's disorder

have no delay in the development of normal expressive and receptive language, including the use of communicative phrases by the age of 3. However, children with Asperger's disorder have problems in their social use of language, for example, being verbose and preoccupied with a favorite topic. Their speech may appear odd due to the use of an unusual accent or the presence of abnormalities in pitch and volume, leading, for example, to a flat and monotonous delivery.

The play, behavior, and daily life of children with autism is usually rigid and repetitive. Their ritualistic play lacks imagination and social imitation. The older children may develop preoccupations with themes such as train timetables or dinosaurs, and this will be the focus of their play, drawing, and conversation. Change or unexpected events can be a significant source of stress: for example, the change of a school timetable.

Approximately 80% of children with autism also have intellectual disability, and a range of other emotional and behavioral disturbances is common. Children with autism who have intellectual (thinking) abilities within the normal range are referred to as high functioning. In contrast, all children with Asperger's disorder have normal intellectual abilities.

High levels of inattentiveness and behavioral hyperactivity are common problems in children with autism and Asperger's disorder; for example, at least 13% of children with autism also meet criteria for ADHD (although a diagnosis of ADHD cannot be made concurrently with a diagnosis of ASD). The overlap of these disorders suggests that ASDs and ADHD share areas of brain dysfunction.

The Neuropsychology of ASDs

There are three main brain theories of autism: theory of mind, the executive dysfunction theory, and the theory of weak central coherence. A poor theory of mind refers to problems with understanding that other people have their own perspectives and thoughts; it is believed to be a reason why people with ASDs have difficulties understanding and relating to other people. The executive dysfunction theory accounts for the problems that people with ASDs experience with timing and planning and producing appropriate and relevant behavior (e.g., coping with changes in the school timetable, planning homework). This breakdown in the ability to effectively direct one's behavior is also thought to be related to the repetitive, stereotyped, and restricted behavioral patterns of ASDs. Weak central coherence refers to a problem with being unable to see the forest for the trees and is thought to be responsible for why people with ASDs tend to be obsessed with details and often miss the bigger picture.

Standardized tests have demonstrated that the neuropsychological profile of autism is characterized primarily by deficient cognitive flexibility and planning, but without problems in the ability to sustain and direct attention (problems attributed to the prefrontal regions of the brain). Research suggests that the kinds of problems that individuals with Asperger's disorder have in directing their behavior may be different from those observed in autism, for example, their problem may be more one of initiating behavior than moving effectively from one behavior to another, perhaps suggesting that different parts of the prefrontal brain are involved in each disorder. Neuromotor testing has found that the walking and upper body postural alignment of people with ASDs is similar to that observed in patients who have Parkinson's disease and patients with cerebellar ataxia, indicating the role of the basal ganglia and cerebellum in these disorders. Again, autism and Asperger's disorder may be associated with different kinds of motor problems, which would suggest the differential involvement of these brain regions.

Neuroimaging Studies in ASDs

Neuroimaging techniques that enable us to look at the structure and function of the brain (e.g., computed tomography [CT], magnetic resonance imaging [MRI], and functional magnetic resonance imaging [fMRI]) have been unsuccessful in revealing a part or function of the brain that is consistently abnormal in all children diagnosed with ASDs. Structural changes in the brains of individuals with autism include a slightly increased average brain volume, a reduction in neuronal integrity in prefrontal areas (an area important for executive functioning – see preceding), decreased gray matter volume in the limbic system (an area important for social understanding), reduced neuron numbers in the vermis of the cerebellum, and gross structural changes in the cerebellum (an area important for motor and cognitive functioning) and the parietal lobes (an area important for efficient attention). fMRI studies have shown decreased activation in the highly interconnected cortical and subcortical frontal structures, suggesting a disconnection between thinking and motor processors in the brain. In summary, the brain imaging research data showing multiple brain region involvement and inconsistencies between people with ASDs fits with the clinical definitions of these disorders as being psychiatrically and neurologically complex and heterogeneous.

Genetics

The cause of the majority of cases of ASD remains unknown, but they are almost certain to have a

multifactorial and complex genetic basis. Autism is associated with defined environmental causes, such as rubella and cytomegalovirus, fetal infections, perinatal brain injury, toxins, and specific genetic abnormalities such as tuberous sclerosis and fragile X syndrome in less than 10% of cases. A higher incidence of prenatal stressors occurring between 21 and 32 weeks of gestation has been associated with the later development of autism. A suggested link between measles, mumps, and rubella vaccination and the use of thiomerosol in vaccines as a cause of the increased prevalence of autism has been discounted by several comprehensive studies.

Attention-Deficit/Hyperactivity Disorder (ADHD)

The symptoms of ADHD may vary in different settings, and diagnosis is often subdivided into the number of symptoms in each of the dimensions of inattention or hyperactivity/impulsiveness. Thus, a child may be diagnosed as ADHD predominately hyperactive type or predominantly inattentive type. Estimates of the prevalence of ADHD vary widely, ranging from 20 to 1–2% depending on the application of diagnostic criteria. The combined inattentive-hyperactive subtype is the most common presentation.

Epidemiology

The childhood prevalence of ADHD is approximately three times higher in males than in females. Symptoms usually reduce with maturation, but at least 30% of children with ADHD will continue to suffer from the disorder in adulthood.

Clinical Features of ADHD

The diagnosis of ADHD is based on a clinical judgment that there are sufficient symptoms of inattention and hyperactivity/impulsiveness, together with the decision that these symptoms cause significant impairment in daily functioning in at least two settings and are not consistent with the developmental level of the child. Therefore, diagnosis requires a careful and comprehensive history of the child's development and behavior from the parents and other informants such as the teacher, together with observation of the child's behavior.

Apart from showing high levels of distractibility and inattention, children with ADHD are disorganized and are usually unable to follow routine or complete tasks. They have difficulty monitoring their behavior and therefore often interrupt others, have difficulty following rules, and display inappropriate and impulsive behavior. Those who also suffer from

hyperactivity are constantly restless and fidgety, have difficulty remaining seated, and behave as if they are driven by a motor. These behaviors are influenced by aspects of the environment, such as the degree of external stimulation and sensory complexity. Therefore, observers may report differences in behavior depending upon the context. For example, a teacher in a busy, noisy classroom setting is more likely to observe inattention than a teacher's aide who meets with the child for individual teaching in a quiet library environment. However, the symptoms and impairments are usually observed, at least to some extent, in all aspects of the child's daily life.

The Neuropsychology of ADHD

In common with ASDs, neurocognitive testing has revealed that ADHD involves deficiencies within the prefrontal regions of the brain described under the umbrella term of executive dysfunction. However, the type of prefrontal executive dysfunction differs between ASDs and ADHD. The classic ADHD profile is characterized by inhibitory deficits and problems with sustained attention, compared to planning and cognitive flexibility deficits in the cognitive profile of children with autism.

Neuroimaging Studies of ADHD

As is the case with ASDs, no consistent structural abnormalities have been recorded for individuals affected by ADHD. ADHD has been associated in some but not all studies with smaller whole brain volumes, right prefrontal anomalies, and structural anomalies in the basal ganglia, cerebellum, and corpus callosum. As is the case with ASDs, fMRI studies have shown decreased activation in the highly interconnected cortical and subcortical frontal structures, particularly in neural regions that subserve key attentional and inhibitory functions.

Genetics and Stressors

The inherited basis for ADHD has been estimated in around 80% of cases, with perinatal brain injury (e.g., caused by stress, alcohol, tobacco, and other substance abuse during pregnancy) responsible for the remainder. The cause in the inherited cases is likely to be a complex interaction of multiple genes, while in some individuals there will also be an interaction with perinatal brain injury or other environmental stressors such as fetal alcohol exposure or postnatal malnutrition. As is the case with ASDs, there has been a large number of candidate gene and linkage studies of ADHD. Genetic screening for ASDs and ADHD is not yet possible.

Stress Associated with Autism and ADHD

Neurodevelopmental disorders present a considerable stress and burden for the affected individual, parents, siblings, and caregivers in the community. The particular stressors change over time and therefore need to be considered in the context of a human life span approach.

Stress Issues from Birth to Preschool

The trajectory of the stress and devastation that accompany a diagnosis of a neurodevelopmental disorder begins for the parents when their child is between 1 and 3 years of age, when parents realize, either through their own observations or through those of others (e.g., extended family, maternal health nurse, general practitioner), that something is not quite right with their child's developmental progress, for example, behavioral deficits in the form of language or social delays, inattentiveness, or behavioral excesses in the form of increased motor activity and hypervigilance. This realization usually triggers a string of subsequent referrals for pediatric, audiological, psychological, and speech and language assessment. Incumbent in each of these referrals is set of neurobiological and developmental test protocols to rule out various diagnoses. For example, a pediatrician may request a series of metabolic (e.g., phenylketonuria) and genetic tests (e.g., fragile X). The psychologist may undertake behavioral and cognitive standardized assessments, while the speech pathologist may request standardized assessments of receptive (i.e., understanding) and expressive (communicative) language. Investigation and testing may occur over a period of 3–12 months, at which time the family will be referred to a specialist (e.g., child psychiatrist, clinical psychologist) or specialist clinic for final diagnostic confirmation. The time length and uncertainty about their child's diagnostic status that parents experience during the assessment process is often stressful.

The formal diagnosis of a neurodevelopmental condition will often trigger a significant grief reaction in parents, who may mourn the loss of their perfect child and be required to reconsider future plans they may have had for their child, e.g., attending particular schools. In the case of ASDs, or when the child has additional severe intellectual disability, there may be a sense of loss about not having grandchildren, as many people affected by these disorders do not go on to partner and have their own children. Furthermore, research has shown that mothers of children with autism are more likely to suffer from depression than mothers of children with other physical conditions (e.g., cystic fibrosis) and mental disabilities.

Parents are typically provided with information about the genetic component of neurodevelopmental disorders at the time of diagnosis. For example, in the case of ASDs, if an older sibling has autism, the risk that a subsequent sibling will have autism is 2–8%. This information is stressful for parents because it has implications for younger siblings and for future family planning.

After a formal assessment has taken place, parents will play an important advocacy role throughout the child's life, a role that requires a significant emotional and financial commitment to ensure that a high quality of life is maintained for their child at each developmental stage. During the preschool years, parental advocacy typically involves organizing appropriate early interventions (e.g., speech and language, occupational therapy, behavioral management). The process of dealing with often lengthy waiting lists to access public services, or self-funding private interventions places a considerable emotional and financial burden on families and may place stress on the larger family unit by increasing work hours for caregivers and reducing time and resources for other family members, in particular, unaffected siblings. Surveys of maternal stress levels have estimated that approximately two-thirds of mothers of children with ASDs experience clinically significant levels of stress when their child is between 2 and 7 years of age. Stress levels are particularly high when a child with ASD has high levels of maladaptive and disruptive behaviors.

Children with ADHD often have hostile interactions with other children (e.g., hitting and biting) during the preschool years. This places a considerable stress not only on parents, but also on the broader preschool community (e.g., parents of other children and teachers). Compared to fathers, mothers have reported that they find these behaviors to be significantly more stressful.

Receiving education about the disorder and skills training in managing problem behaviors, learning relaxation and stress management techniques, and increased social support (e.g., respite care and community support groups) have been found to be useful for improving parental mental health and reducing parental stress associated with having a child with a neurodevelopmental condition.

Stress Associated with the Primary School Years

Interventions put in place during preschool years will typically continue into the primary school years depending on the availability of community and privately funded resources. During the school years, parents often become concerned about their child's

education and adverse school experiences such as being teased. They focus on advocating for appropriate educational modifications and placements to promote their child's ability to reach individual academic potential and to experience a safe and supportive school environment. This usually involves families again seeking out the services of psychologists and speech pathologists so that their child can have updated assessments of language and cognitive ability. This process is a burden for children and parents because it is time consuming and costly. In some cases, at the end of such assessment processes, children are deemed ineligible for education aide support or special consideration because of bureaucratic and funding reasons (e.g., the child's IQ is 72 points rather than 70 points). This issue sometimes requires higher levels of advocacy from involved health professionals to assist parents with appeal processes.

For children with autism who have good early intervention, focused on the parent (e.g., behavior management training, psychoeducation) as well as the child, disruptive behaviors are manageable, and the quality of life for the child and family is generally improved. For children who do not receive good early interventions, or when standard interventions are inadequate, perhaps due to additional neurobiological comorbidity and ongoing disruptive behaviors (e.g., stubbornness, self-injury, and aggression), there is an increased risk of failure in school and community activities, in some cases leading to more restrictive care. When psychological and behavioral interventions have not been successful in the management of disturbed emotions and behaviors, which may be underpinned by high levels of anxiety, treatment with neuroleptic medication (e.g., haloperidol, risperidone, imipramine, clomipramine, fluoxetine) that targets specific symptoms might prove helpful.

While the antisocial behavioral tendencies (e.g., biting and hitting) of children with ADHD may subside with good management during the preschool years, for older children poor management and associated comorbidity (e.g., conduct disorder and oppositional defiant disorder, learning disorders) increase the chances of school failure and peer rejection. Comorbidity with oppositional defiant disorder (e.g., clashing verbally with authorities) has been suggested at between 32 and 60%, while comorbidity with conduct disorder (e.g., engaging in theft) has been estimated at anywhere between 12 and 25%. Stimulant medications (e.g., methylphenidate and dexamphetamine) are effective treatments for the symptoms of ADHD. Side effects, which may include decreased appetite, insomnia, fatigue, irritability, and increase in pulse rate and blood pressure, may be a

source of stress for the individual and for parents. Tricyclic antidepressants (imipramine) clonidine, or atomoxetine (an inhibitor of the presynaptic norepinephrine transporter) are alternative treatments for children who have intolerable side effects or are unresponsive to stimulant medication. Parents may be stressed by the uncertainty of potential long-term effects of placing their child on medication. Currently there is a lack of good long-term evidence for the effectiveness of stimulant medication on learning, but they may decrease the risk of later substance abuse.

Stress Associated with the Secondary School Years

In the normal scheme of development, the transition from a relatively protected and highly structured primary school setting to secondary school is often a time of stress for children and families; these concerns and issues are magnified when a child has a neurodevelopmental disorder. In contrast to primary school, secondary school is often larger and requires the young person to be independent, navigate the school timetable, and engage in homework. All of these activities require good executive functions, e.g., planning, preparation, and anticipation, skills classically affected by neurodevelopmental disorders.

Adolescence is a developmentally complex time defined by social and sexual development and identity formation. Because social understanding and adaptability are innately reduced in ASDs it is an especially complex time for these young people. The affected young person may be more stressed than their nonaffected peers as they go through puberty and deal with changes in physical body shape, development in their thinking and insight, and emerging sexuality. Stress is also elevated for those individuals who develop comorbid psychiatric conditions, particularly depression, during this time. Depression may manifest as mood disturbance and irritability, sleep and appetite disturbance, and thoughts of suicide that may be enacted. The increased vulnerability to depression during adolescence may be associated with self-awareness of the disability, pubertal brain development, and a family history of depression. Stress and anxiety have been associated with the onset of tic disorder, or Tourette syndrome, in young people with ASDs. There is also an increased risk of developing psychosis during adolescence or early adult life, particularly for young people with Asperger's disorder. Individuals with associated intellectual disability are at greater risk for developing epilepsy during the adolescent and early adult years.

In addition to ongoing issues that first emerge in the primary school years (e.g., associated learning difficulties estimated in up to 50% of children with

ADHD) for young people affected by ADHD and their families, new hazards during secondary schooling revolve around ongoing and escalating child-parent conflicts, delinquent behavior, substance abuse (e.g., nicotine, alcohol, and illicit drug use), and an increased risk of being involved in car accidents, all of which may lead to school suspensions, community marginalization, and an increased risk of a breakdown of family relationships. It has been noted that increased marital discord when a child in the family has been diagnosed with ADHD may be influenced by the parents themselves having ADHD, given the associated genetic vulnerability. Young people who are treated with stimulant medication for ADHD are less likely to use substances compared with adolescents with ADHD who are not receiving treatment.

In contrast to individuals with ADHD, individuals with ASDs often go to lengths not to use drugs and alcohol, an issue that may paradoxically cause stress and social conflict because the individual with ASD may feel driven to impose their rigid views about abstinence onto unsuspecting others, for example, taking a cigarette or alcoholic beverage out of the hand of a friend or restaurant patron.

Stresses during Adulthood

For people affected by ASDs, the adulthood stressors vary widely according to the individual's intellectual ability, capacity for independent living, and provision of social, emotional, financial, and occupational support. It has been suggested that individuals with associated intellectual disability and epilepsy are at greater risk for deterioration during early adulthood, while there may be some improvement in functioning in normally intelligent young adults with ASDs. People with moderate to profound intellectual ability may be placed in special housing accommodation or residential care, depending on the family's emotional and financial ability to retain care within the family unit. This time of transition may be particularly stressful for the individual because it involves adaptation to a new environment and many changes in daily routine. Transition is stressful for family members involved in the decision-making process because they often feel a great sense of guilt and loss. Thus, the grieving process over the loss of the young person's potential, which begins for parents when they first come to terms with the diagnosis, is often revisited at this developmental point. Alternatively, the prospect of providing continuing care, without the hope of relief, is a source of anxiety for aging parents.

Even when young people with ASDs have relatively intact intellectual ability (e.g., ranging from mildly impaired to normally intelligent), they remain greatly

impaired in their ability to process social information. Like the transition from primary school to secondary school, the transition to adulthood involves another leap of independence, involving a greater need for executive abilities (e.g., budgeting money, planning meals) and social adjustment. Indeed, the social rules may become even more perplexing for an adult with ASDs, as the immediate supports and supervision from parents, teachers, and school aides reduce or disappear as the young person is expected to live independently in the community. The transition to adulthood is perhaps more complex for individuals who have poorer adaptive and life skills, with a lack of early intervention and skills training and poor management of associated comorbid psychiatric conditions such as anxiety during the formative years.

Reduced social ability and obsessional characteristics associated with ASDs may put an individual at greater risk for being unwittingly involved in inappropriate or illegal behavior, for example, sexual offending or stalking, which may occur in the context of naive and inept attempts to make social contact. Similarly, there have been reports in the Australian and European media about individuals with ASDs stealing trams or trains to pursue an obsessional interest in the rail system. Interventions to manage these types of forensic issues may be punitive and inappropriate, particularly when the individual's diagnosis may not be known, leading to additional feelings of being rejected and further emotional and behavioral problems.

Adults with ADHD are usually less disruptive and hyperactive than children with ADHD, but usually remain somewhat impulsive, disorganized, inattentive, and restless or lack motivation. Young adults with comorbid conduct disorder and an inability to control their behavior are at increased risk for being in trouble with the law, ranging from accumulating multiple speeding fines to committing more significant crimes, such as robbery. The disinhibited, poorly focused, and overactive symptoms of those with ADHD may make it difficult to maintain employment and social and stable intimate relationships.

Conclusion

ASDs and ADHD are lifelong neurodevelopmental conditions, possibly involving overlapping brain regions, that are associated with numerous and accumulating individual stressors across the life span. Despite the many differences between ASDs and ADHD, there are many commonalities in the factors that may protect against or lessen the impact of these stressors. At the forefront of these is the availability of early interventions, parent support and guidance, and ongoing management at key developmental stages from health, education, and welfare services (e.g., general practitioners, psychologists, psychiatrists). These may prevent the accumulation of stressful events and related complications that significantly reduce the quality of life of the affected individual and family and are costly to society with an increased prospect of unemployment, family and relationship breakdown, legal issues, and psychiatric care.

Glossary

<i>Action potentials</i>	Electrical impulses that propagate signals along nerve fibers. The potentials are produced by the flux of ions, in particular sodium and potassium ions, through ion channels along the nerve cell membrane.
<i>Exocytosis</i>	The release of a secretory product, including neurotransmitters, in packets or quanta. The secretory products are packaged by the Golgi apparatus of the cell in membrane-bound vesicles. Exocytosis involves fusion of the vesicular membrane with the cell membrane, resulting in the release of the quantum of product inside the vesicle. This is thought to be the major mechanism of secretion in most secretory cells, including neurons.
<i>Limbic system</i>	The system comprising a number of structures, all interconnected, to form a circuit that is concerned primarily with emotions, memory, olfaction, and neuroendocrine control; gets its name from the fact that it forms a border between the new and old (in evolutionary terms) brains.
<i>Neurohemal junction</i>	A specialized junction between nerve terminals and a plexus of capillaries that facilitates the transport of neurohormones from the nervous system into the bloodstream or <i>vice versa</i> .
<i>Neurohormone</i>	A chemical substance released from nerve terminals and transported to its target cells by the bloodstream. Neurohormones

are often the same chemical substances as neurotransmitters.

Neurosecretion

The secretion of hormones by nerve cells.

Neurotransmitter

A chemical compound released by nerve cells (at nerve synapses or neuromuscular junctions) that either excites or inhibits a target cell. The target cell may be another nerve cell, glandular cell, or muscle fiber. Chemical neurotransmission is widely used in the nervous system and, because it is capable of analog functions, has a considerable advantage over electrotonic transmission, which is necessarily digital.

Portal vessels

The vessels that transport blood and solutes from one capillary bed to a second capillary bed before joining the systemic circulation. The hypophyseal portal vessel system transports neurohormones released from hypothalamic nerve terminals into a primary capillary plexus in the median eminence to a secondary capillary–sinusoidal plexus in the pituitary gland.

Steroid hormones

Molecules composed of a basic fused unit of three 6-membered (cyclohexane) and one 5-membered (cyclopentane) carbon rings with a variety of functional groups attached. The large number of carbon–hydrogen bonds makes steroids nonpolar.

Stimulus secretion coupling

The link between a stimulus, usually membrane depolarization (axon potentials in the case of nerve cells), and the release of a neurotransmitter or neurohormone.

Synapse

A specialized junction between two nerve cells where signaling most commonly occurs by way of the release of neurotransmitters.

Introduction

The human pituitary gland weighs no more than one gram, but it nonetheless controls all the major endocrine systems and is indispensable for life. Located at the base of the brain and closely surrounded by protective dense bone and fibrous membranes, the gland is composed of the neurohypophysis or neural lobe and the adenohypophysis. Derived embryologically from a neural downgrowth, the neural lobe is composed of axons that project from nerve cells in the hypothalamus and terminate on capillaries of the

inferior hypophysial artery. This is the site at which arginine vasopressin (AVP) (lysine vasopressin in pigs) and oxytocin are released into the systemic circulation. Synthesized in the supraoptic nucleus (SON) and paraventricular nucleus (PVN), AVP, also called the antidiuretic hormone, controls the volume of body water, whereas oxytocin is concerned mainly with stimulating milk ejection during lactation and contraction of the uterus (womb) during parturition.

The adenohypophysis is derived from an outgrowth of the roof of the mouth and, in subhuman species, is divided into the pars distalis and the pars intermedia. The pars distalis is more commonly called the anterior lobe, whereas the pars intermedia together with the neural lobe or pars nervosa forms the posterior lobe. There is no distinct pars intermedia in the human. The anterior pituitary gland secretes hormones that control the adrenal and thyroid glands, the gonads, body growth, and development of the breast and lactation. The hormones involved in this pituitary control are, respectively, adrenocorticotrophic hormone (ACTH), thyrotropin (TSH, thyroid stimulating hormone), the gonadotropins, growth hormone (GH), and prolactin. In addition to being growth promoting (trophic) and stimulating immediate hormonal or cellular events (tropic), these hormones all affect metabolism. The loss of ACTH with the consequent loss of adrenocortical hormone secretion, and perhaps to a lesser degree GH and TSH, makes removal of the gland (hypophysectomy) lethal.

Although ACTH is considered to be the main anterior pituitary stress hormone, GH and prolactin are also released in response to stress and so receive special attention in this article. Thus, for example, insulin-induced hypoglycemia is a potent metabolic stress that, in humans, results in a massive and rapid release of GH. Stress-induced prolactin release may, under certain circumstances, be causally related to infertility.

Anterior pituitary hormone secretion is under central nervous system (CNS) control and is modulated by the feedback of hormones secreted by the pituitary target organs: the adrenal and thyroid glands, the gonads, and, as shown recently, fat tissue by way of adipokines such as leptin and adiponectin. Neural control of the anterior pituitary hormones is mediated by the hypothalamic-pituitary regulatory neurohormones (formerly termed factors), which are released from the hypothalamus into the hypophysial portal vessels and transported by them to the anterior lobe, where they either stimulate or inhibit the release of the anterior pituitary hormones. The hypothalamic-pituitary regulatory factors are now termed neurohormones because, instead of being released at

synapses, they are released and transported to their target cells in the bloodstream.

The hypothalamic-pituitary system is the interface between the CNS and the endocrine system by which external factors, such as stress and day length, and internal factors, such as emotion, trigger endocrine responses. It was therefore termed the neuroendocrine system, and the pituitary gland is said to be under neuroendocrine control. In addition to the hypothalamic-pituitary system, the circumventricular organs also satisfy the criteria of neuroendocrine systems. The term neuroendocrine is also applied to interactions between nerve and endocrine cells in the periphery and especially the viscera, of which the gastrointestinal system and its appendages (especially the pancreas) are the most prominent. Of special relevance to stress is the sympathetic component of the autonomic nervous system and the adrenal medulla. Derived from the embryonic neural crest, the cells of the adrenal medulla are modified postganglionic neurons that secrete their neurotransmitters, mainly adrenaline (epinephrine) and opioids, directly into the bloodstream.

The present article focuses on the principles of neuroendocrine control of the pituitary gland and illustrates how the hypothalamic-pituitary system (1) was used to demonstrate that certain peptides satisfy the criteria of neurotransmitters or neurohormones; (2) played a significant role in our understanding of gene transcription, translation, and posttranslational processing; and (3) could be used as a window to study brain function in the conscious human (neuroendocrine window of the brain). Although only mentioned briefly in this article, neuroendocrinology is also concerned with the effects of pituitary target hormones on the brain-pituitary system, that is, on the way that hormones secreted by the anterior pituitary target glands play an important role in brain differentiation and plasticity; affect central neurotransmission and thereby mood, mental state, and memory; and exert feedback effects on the brain-pituitary system. These hormonal feedback systems constitute the afferent limb of homeostatic regulatory systems, which ensure that the output of pituitary hormones is maintained at a preset and functionally optimal level.

Hypothalamic-Pituitary Axis

Brief History

The central importance of the anterior pituitary gland as conductor of the endocrine orchestra was not understood until the early 1930s when P. E. Smith published his parapharyngeal method for removing

the gland (hypophysectomy). The effects of hypophysectomy proved to be so dramatic that for a short period most scientists in the field, including the distinguished neurosurgeon, Harvey Cushing, thought that the pituitary gland was autonomous. However, around the same time, William Rowan, working in Alberta on the annual migration of birds, showed that day length had a potent effect on the growth of the gonads. Rowan's experiments, together with those on seasonal breeding in animals, the effects of stressful stimuli on endocrine organs, and the effects of brain lesions on pituitary hormone secretion led to the concept that the anterior pituitary gland must be under CNS control, a view that Cushing soon adopted. The observational and experimental evidence that supported this concept was summarized by F. H. A. Marshall in his 1936 Croonian lecture.

It had long been known that the pituitary gland and brain were connected by the pituitary stalk, but several lines of evidence suggested that neural control of the anterior pituitary gland was mediated not by nerve fibers in the pituitary stalk but by chemical substances released into the hypophyseal portal vessels. These vessels, first described by G. T. Popa and U. Fielding in 1930, surround the pituitary stalk, linking a primary plexus of capillaries at the base of the hypothalamus with a second capillary plexus in the anterior pituitary gland. Throughout the 1930s and 1940s, a debate raged about the direction of blood flow in the hypophyseal portal vessels. Based on histological evidence, this debate could have been avoided had someone read the 1935 report by Bernado Houssay and associates that in the living toad blood flowed from the hypothalamus down to the pituitary gland. But Houssay's paper was published in French.

The neurohumoral hypothesis of the control of the anterior pituitary gland was first formally advanced by H. B. Friedgood in 1936 and J. C. Hinsey in 1937. However, it was the elegant pituitary graft experiments of G. W. Harris and Dora Jacobsohn that showed beyond doubt that the anterior pituitary gland was controlled by substances released at nerve terminals in the median eminence at the base of the hypothalamus and transported to the pituitary gland by the hypophyseal portal vessels. The characterization of the first three of these substances, thyrotropin-releasing factor (later thyrotropin-releasing hormone, TRH), luteinizing hormone-releasing factor (LRF; later, luteinizing hormone-releasing hormone, LHRH; or gonadotropin-releasing hormone, GnRH), and somatostatin, was to take a further 18–21 years of hard work in the laboratories of Roger Guillemin and Andrew Schally, for which they were awarded the 1977 Nobel Prize for Physiology and Medicine.

The sequence of corticotropin releasing factor-41 (CRF-41; later, corticotropin releasing hormone, CRH-41) was determined by Wylie Vale and associates in 1981, a breakthrough that had eluded many workers for more than 25 years.

Soon after its characterization as a decapeptide in 1971, G. Fink and M. Jamieson measured LHRH by radioimmunoassay in hypophyseal portal blood of the anesthetized rat and showed that its release could be increased fivefold by a small electrical stimulus applied to the medial preoptic area of the hypothalamus. The neurohumoral hypothesis of neural control of the anterior pituitary control had been proved.

General Anatomy and Development

The pituitary gland is anatomically linked to the hypothalamus at the base of the brain by way of the pituitary stalk ([Figure 1](#)). The hypothalamus comprises a medial part adjacent to the third cerebral ventricle, in which are located the major hypothalamic nuclei, and a lateral part made up mainly of a large cable of nerve fibers that carries reciprocal fiber tracts between midbrain and forebrain, the medial forebrain bundle ([Figure 2](#)), in which are embedded aggregations of nerve cell bodies. Axons from nerve cell bodies located in the hypothalamic nuclei project to the median eminence, where they either terminate on the loops of primary capillaries of the hypophyseal portal vessels in the external layer of the median eminence or form a cable that passes through the internal layer of the median eminence to form the bulk of the pituitary stalk and then the neural lobe ([Figure 3](#)). The median eminence, so called because it protrudes as a small dome in the midline from the base of the hypothalamus, forms the floor of the third ventricle and is delineated by the optic chiasm in front, the mamillary bodies behind, and a depression (hypothalamic sulcus) on either side. Arising from the median eminence is the neural stalk, which links the pituitary gland to the brain.

The pituitary gland is located in a fossa in the basisphenoid bone at the base of the skull, the sella turcica (so called because its shape resembles a Turkish saddle). The close proximity of the hypothalamus and pituitary gland to the optic chiasm means that tumors in either the hypothalamus or the pituitary gland may press on, or more rarely invade, the optic chiasm or tracts, thereby leading to visual defects.

The hypothalamic-pituitary axis is divided functionally into two systems ([Figure 4](#)): the hypothalamo-adenohypophyseal axis (the hypothalamus, hypophyseal portal vessels, and adenohypophysis) and the hypothalamo-neurohypophyseal axis (the hypothalamus, neural stalk, and neural lobe). The neural stalk is made up of numerous nerve fibers that project

Figure 1 A midsagittal section of the human brain showing the inside (medial) surface. Note the pituitary gland attached by way of the pituitary stalk to the floor of the hypothalamus. The hypothalamus and the thalamus, which lies above it, form the wall of the third cerebral ventricle, at the posterior end of which is the pineal gland.

mainly from the PVN and SON of the hypothalamus to terminate on a capillary bed derived from the inferior hypophysial artery and located in the neural lobe of the pituitary gland. Nerve fibers in the neural lobe (or pars nervosa) are surrounded by pituicytes, the equivalent of glial cells. Also present in the neural stalk are nerve fibers of other types of chemical neurotransmitter (in addition to AVP and oxytocin), such as the endogenous opioids and dopamine, which are present in nerve fibers that project from the arcuate nucleus and innervate the pars intermedia. Because the stalk and median eminence are continuous, these dopaminergic neurons are a continuation of a dense palisade of dopaminergic fibers that also terminate on the primary plexus of the hypophysial portal vessels enmeshed with nerve fibers that contain other neurohormones. The pituitary stalk and median eminence are covered by a single layer of cells termed the pars tuberalis, which is continuous with the pars distalis.

The adenohypophysis develops from an outgrowth of the ectodermal placode, which forms the roof of

the embryonic mouth (or stomadeum). This ectodermal outgrowth forms Rathke's pouch and meets the neurohypophysis, which grows down from the floor of the embryonic third ventricle. Rathke's pouch closes and separates from the roof of the mouth. The caudal (rear) part of the pouch remains thin to form the pars intermedia, which becomes tightly juxtaposed to the rostral surface of the neurohypophysis ([Figure 5](#)). The rostral part of the pouch develops into the pars distalis ([Figure 5](#)). Vascularization of the median eminence and the pituitary gland begins on approximately day 15 of embryonic life (E15) in the rat, and the hypophysial portal vessels become defined by E18. Nerve terminals in the median eminence with granular vesicles (presumably neurohormones) are first evident on E16 and the first secretory granules appear in pars distalis cells on E17. This sequence of embryonic development suggests that the development of secretory cells in the pars distalis may depend in part on the development of nerve terminals in the median eminence and the anlage of the hypophysial portal vessels.

Figure 4 Schematic diagram of the hypothalamic-pituitary system showing the magnocellular (white) projections directly to the systemic capillaries of the pars nervosa (PN) and the parvocellular (black) projections to the primary plexus of the hypophyseal portal vessels, which convey neurohormones to the pars distalis of the anterior pituitary gland (AP). Dorsal to the optic chiasm (OC) are suprachiasmatic nuclei (SC), which receive direct projections from the retina and play a key role in the control of circadian rhythms (indicated by the sinusoidal curve). Activity of the intrinsic neurons of the hypothalamus is influenced greatly by projections (arrows) from numerous areas of the forebrain, midbrain, and hindbrain, particularly the limbic system, as well as by hormones, mainly estrogen and progesterone in the case of the hypothalamic-pituitary-gonadal system.

Neurohemal Junctions and Circumventricular Organs

Neurohemal junctions are the fundamental functional modules of the major central neuroendocrine system, the median eminence. They are composed of nerve terminals and capillaries that are closely juxtaposed and thereby facilitate the transport of chemical messengers from nerve terminals into the bloodstream and *vice versa* (Figure 6). Neurohemal junctions are also the fundamental units of the neurohypophysis and of the circumventricular organs, such as the organum vasculosum of the lamina terminalis, the subfornical organ, and the pineal gland, which are located at various sites around the third

Figure 5 Photomicrographs of midline sagittal sections through the hypothalamic-pituitary complex showing the development of the pituitary gland in the rat. a, On embryonic day 15 (E15; $\times 120$); b, on E17 ($\times 120$); c, on E20 ($\times 80$). In a, the pituitary anlage shortly after closure of Rathke's pouch, which migrates dorsally to meet neurohypophysial downgrowth from the floor of the hypothalamus. Rotation of the pituitary gland caudally through 135° with respect to the base of the diencephalon (hypothalamus) is seen, as is the invasion of the pars distalis (PD) by the leash of portal vessels (P) on E17. (1971), Ultrastructural features of the developing hypothalamo-hypophysial axis in the rat, *Zeitschrift für Zellforschung und mikroskopische Anatomie* **119**, 208–226.

cerebral ventricle, and the area postrema, located in the floor of the fourth cerebral ventricle. All the circumventricular organs are characterized by the fact that their vessels are fenestrated (Figure 6) and that the blood–brain barrier is inoperative at these sites. The neurohemal junctions in the median eminence, neurohypophysis, and pineal gland facilitate the transport of neurohormones from the nerve terminals or nerve cell derivatives (pineal) into the bloodstream, whereas at the other circumventricular organs, neurohemal junctions facilitate the transport of neurohormones from the blood to nerve cells. The latter mechanism has been implicated in the cross-talk between peripheral organs and the brain so that, for example, the hypertensive effect of the peptide, angiotensin, is due in part to its activation of neurons of the subfornical organ, which have a high density of angiotensin receptors. In addition to their importance as sites for the transfer of chemical messengers from nerve terminals into blood vessels, and *vice versa*, the neurohemal junctions of circumventricular organs are also sites at which drugs or toxins, which are

normally excluded by the blood–brain barrier, can penetrate the brain and affect brain function.

The Hypothalamo-Adenohypophysial System

Neurohormonal Control of Anterior Pituitary Hormone Secretion

The transmission of signals between the brain and the anterior pituitary gland is mediated by chemical messengers called neurohormones, which are transported by the hypophysial portal vessels from the hypothalamus to the anterior pituitary gland (Figures 3–5) where they either stimulate or inhibit the release of anterior pituitary hormones. Synthesized in nerve cells of the hypothalamic nuclei, the neurohormones are released from nerve terminals into the plexus of primary capillaries of the hypophysial portal vessel system. These capillaries are derived from the superior hypophysial arteries and coalesce to form the hypophysial portal veins, which run on the

Figure 6 Electromicrograph of the external layer of the median eminence of a rat on the first postnatal day ($\times 13,200$). Note the high density of nerve terminals around part of a primary portal capillary vessel (P), which is fenestrated (F). Note also the large number of agranular and granular vesicles in the nerve terminals. These vesicles contain the packets (quanta) of neurohormone or neurotransmitter that are released on nerve depolarization as a consequence of nerve action potentials. The neurohormones are released into the perivascular space and from there move rapidly into portal vessel blood for transport to the pituitary gland. This arrangement is typical of neurohemal junctions found in the several circumventricular organs of the brain. E, endothelial cell; G, glial process; PVC, perivascular cell; PVS, perivascular space. Reproduced with permission from Fink, G. and Smith, G. C. (1971), Ultrastructural features of the developing hypothalamo-hypophysial axis in the rat, *Zeitschrift für Zellforschung und Mikroskopische Anatomie* **119**, 208–226.

surface or through the pituitary stalk to the anterior pituitary gland, where they form a secondary plexus of vessels called the pituitary sinusoids. Vessels on the surface of the stalk are the long portal vessels, whereas those within the substance of the stalk are the short portal vessels.

Hypophysial Portal Vessels

The portal vessels are so called because they transport chemical messengers from one capillary bed (primary capillaries) to a second capillary bed before entering the general circulation. In principle, this is identical to the hepatic portal system, which transports substances from the primary bed of capillaries in the intestine and its appendages (e.g., the pancreas) to a second bed of capillaries or sinusoids in the liver. Fenestration of the primary and the secondary (sinusoids) plexus of capillaries (Figure 6) facilitates the transport of substances across the capillary wall. Hormones released from anterior pituitary cells are transported by pituitary veins into the systemic circulation by which they are transported to their major target organs, the gonads and the adrenal and thyroid glands.

Hypothalamic Neurohormones

Outline Most of the neurohormones that mediate the neural control of anterior pituitary hormone secretion are peptides that are synthesized in discrete hypothalamic nuclei. Neurohormone-secreting neurons are the final common pathway neurons for neural control of the anterior pituitary gland, a term borrowed by G. W. Harris from Sherrington's description of the alpha-motor neurons of the spinal cord that innervate and control the contraction of skeletal muscles. Like the alpha-motor neurons, hypothalamic neurons are controlled by inputs to the hypothalamus from the brain stem, midbrain, and higher brain centers. The hypothalamic neuroendocrine neurons are thus connected with many other regions of the nervous system and, in particular, the components of the limbic system, which is involved in higher brain functions, including emotion, olfaction, and memory.

The neural control of all established anterior pituitary hormones is mediated by at least one or more neurohormones. In some cases, two neurohormones may act synergistically, as is the case of ACTH, the release of which is stimulated by both the 41-amino-acid-residue peptide CRH-41 and the nonapeptide AVP. The control of ACTH secretion is further complicated by the fact that urocortins, relatively new members of the CRH-41 family of peptides, act mainly by way of CRH type 2 receptors in the PVN to modulate AVP and CRH-41 synthesis. Hypophysial portal blood and immunoneutralization studies suggest that ACTH secretion may be inhibited by atrial natriuretic peptide (ANP).

In other cases two neurohormones may act antagonistically, as is the case for GH, whose release is stimulated by the 44-amino-acid-residue peptide GH-releasing hormone (GHRH-44) and inhibited by the 14- or 28-residue peptide somatostatin-14 or -28. The neural regulation of pituitary GH secretion is even more complex than originally thought; Bowers and associates discovered in 1981 that a hexapeptide, referred to as GH-releasing peptide-6 (GHRP-6), is a potent GH secretagogue. Subsequent studies showed that GHRP-6 binds to a receptor, GH secretagogue receptor (GHS-R), that is distinct from the GHRH-44 receptor. The endogenous ligand for the GHS-R is ghrelin, a 28-amino-acid-residue peptide secreted mainly by neuroendocrine cells of the gastric mucosa, which also stimulates GH release.

Prolactin seems to be the only anterior pituitary hormone that is predominantly under the inhibitory control of the brain. Evidence for this came first from the studies of Everett and Nikitowitch-Winer, who showed that prolactotrophs were the only cell type

that did not undergo atrophy in pituitary grafts under the kidney capsule, where they are far removed from central neural control. This histological observation was confirmed by the finding that prolactin concentrations in plasma are increased in animals bearing pituitary grafts under the kidney capsule. There is substantial evidence that dopamine, released into hypophyseal portal blood from tuberoinfundibular dopaminergic neurons, inhibits prolactin release. Indeed, dopamine agonists such as bromocriptine, cabergoline, and quinagolide are highly effective in treating hyperprolactinemia, a relatively common cause of infertility in women. Dopamine is now regarded as the prolactin inhibitory factor (PIF). Hyperprolactinemia is frequently due to benign tumors (adenomas) of the anterior pituitary gland, and these too can often be controlled by treatment with dopamine agonists. Stress is another common cause of hyperprolactinemia. Indeed, the prolactin response to stress in the human is as sensitive as that of ACTH and adrenal glucocorticoid response to stress.

The search for a prolactin-releasing factor (PRF) has continued for many years. Potential candidates have included TRH, vasoactive intestinal peptide, GnRH-associated peptide (GAP), and two novel, closely related hypothalamic peptides (termed PrRP31 and PrRP20) discovered in 1998 by Hinuma and associates when searching for a ligand for an orphan receptor (hGR3). Recent evidence suggests that the peptides intermedin and adrenomedullin may also release prolactin. However, although all these compounds are capable of stimulating prolactin release from pituitary cells *in vitro*, and in some cases under pharmacological conditions *in vivo*, robust proof that any of these compounds are the physiological PRF remains to be established.

The neural control of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), is mediated by one and the same decapeptide, GnRH.

Criteria for neurohormones and neurotransmitters Werman, in 1972, summarized the criteria for classifying a candidate compound as a neurotransmitter or neurohormone thus: "If it can be shown that a substance is released into the extracellular space from presynaptic nerves in quantities consistent with the amount and rate of stimulation and the physiology of transmitter release at that junction, and if it can be shown that the material released acts on postsynaptic membranes by using molecular mechanisms identical with those used by the physiologically evoked transmitter, then that substance is a transmitter." Werman's two principal criteria – endogenous release (collectibility) and exogenous

mimicry (identity of action) – should be supplemented by a third criterion invoking the topochemistry of the mechanisms for the synthesis and inactivation of the transmitter.

The technique of collecting hypophyseal portal blood in the anesthetized rat (developed by Fink and Worthington in 1966) has made it possible to satisfy these criteria for all the hypothalamic-pituitary neurohormones outlined here, as well to clarify the mechanism and physiological significance of post-translational processing. The measurement of neurohormone release into the hypophyseal portal blood has also made it possible to ascertain whether newly discovered hypothalamic compounds could serve as hypothalamic-pituitary regulatory factors. This is exemplified by work in our laboratory, which showed that the concentrations of the cardiac peptide ANP were about four times greater in portal than in systemic blood, a finding that led to immunoneutralization studies that suggest that ANP is an ACTH-inhibiting factor. Studies of hypophyseal portal blood can also exclude the neurohormonal role of a candidate neurotransmitter. Thus, for example, although immunohistochemistry suggests that angiotensin and cholecystokinin are both present in the median eminence, their concentrations in portal blood are not greater than in peripheral blood, which makes it unlikely that either plays a role as a neurohormone.

All the hypothalamic-pituitary regulatory neurohormones are present in regions of the nervous system outside the hypothalamus, where Werman's criteria for a neurotransmitter need to be proved by determining whether the neurohormones are released (by push-pull cannulae or dialysis), activate cells (e.g., electrophysiologically), and are responsible for a behavioral effect. The functional significance of neurohormone action in areas of the CNS outside the hypothalamus is illustrated poignantly by CRH-41, which is believed to synchronize the endocrine, autonomic, immunological, and behavioral responses to stress.

Neurohormone receptors The hypothalamic neurohormones and their receptors, all members of the G-protein-coupled, seven transmembrane superfamily, underscore the adage that the evolution of hormones is less dependent on structural changes in the hormones than on the uses to which they are put. The latter depends entirely on the receptors and the signal transduction systems that mediate receptor activation, a point illustrated by the receptors that mediate the neurohormone control of ACTH and GH secretion.

The actions of CRH-41 in brain and periphery are mediated by two main receptor subtypes, CRH1 and

CRH2, with splice variants CRH2 α and CRH2 β . A third CRH receptor has recently been discovered in catfish pituitary. cAMP-linked CRH receptors also mediate the action of the urocortins, the mammalian homologs of urotensin in fish, and of sauvagine, a homolog of CRH-41 derived from the South American tree frog. In addition to mediating the neural control of ACTH release, CRH-41 and the urocortins exert actions on the brain and the cardiovascular system. CRH1 receptors (1) are localized predominantly in brain and pituitary, (2) have a high affinity for CRH-41, (3) are expressed by pituitary corticotrophs, and (4) are responsible for mediating the stress-induced CRH-41 stimulation of ACTH release. CRH2 receptors have a greater affinity for the urocortins than for CRH-41 and are present mainly in heart and skeletal muscle. However, the CRH2 α splice variant is also present in brain and pituitary gland, where it is expressed by pituitary gonadotrophs, but not corticotrophs, leading to the suggestion that CRH2 α may mediate stress effects on gonadotropin secretion. The ACTH-releasing action of CRH-41 is potentiated by AVP, which binds to the V $_{1\beta}$ receptor. The V $_{1\beta}$ receptor activates the inositol phospholipid cycle. Synergism between CRH-41 and AVP involves calcium-activated cAMP production. ACTH secretion is inhibited by ANP, an action mediated by two guanylyl cyclase-coupled receptor subtypes: A and B.

Human GHRH receptor cDNA was first cloned and sequenced in Mike Thorner's laboratory in 1993 and was found to be a member of a family of receptors that includes secretin, calcitonin, vasoactive intestinal peptide, and parathyroid hormone. The activity of the GHRH receptor (GHRH-R) promoter is enhanced by the pituitary-specific transcription factor POU1FI (formerly Pit-1). The importance of POU1FI, the prototypic POU-homeodomain transcription factor, for the development and activity of the GHRH-R is demonstrated by the fact that the GHRH-R is not present in the pituitary gland of dwarf mice (*dw/dw*) that lack POU1FI. Glucocorticoids stimulate, whereas estrogen inhibits, GHRH-R gene expression, actions that are likely to be mediated by the glucocorticoid and estrogen response elements present in the promoter and that explain in part the physiological effects of glucocorticoids and estrogen on GH secretion. The pituitary expression of GHRH-R mRNA in the rat increases with embryonic development to reach a peak at E19.5 (2 days before parturition), followed by a decline through to postnatal day 12 and then an increase to day 30, followed by a decline with age. If a similar pattern occurs at the corresponding times in humans, then that could be a major factor in the decline in plasma GH

concentrations with age in the elderly. The GHRH-R is distinct from the GHS-R whose ligand is the 28-amino-acid-residue gastric peptide ghrelin. Both types of receptor are members of the seven-transmembrane helix, G-protein-coupled receptor family.

There are six receptors for somatostatin (SSTR), encoded by five distinct genes. All six receptors are present in the anterior pituitary gland; SSTR-5 is the most prominent on the somatotrophs, followed by SSTR-2 (which has splice variants A and B). Hypothalamic arcuate neurons that secrete GHRH express SSTR-2 and SSTR-1, supporting the proposition that the action of somatostatin may involve an effect on the release of GHRH. Relatively large amounts of somatostatin are also present in the cerebral cortex and hippocampus, regions that express the SSTR-2A. In the periphery, somatostatin secreted by pancreatic islet cells inhibits the secretion of insulin, glucagon, and a range of gut peptides.

The complexity of the receptors involved in the control of ACTH and GH secretion contrasts with the apparent simplicity of the gonadotropin control system, in which GnRH mediates the neural control of both LH and FSH, and the apparent simplicity of the thyrotropin and prolactin control systems, in which there is evidence, so far, for only one neurohormone each, TRH and the PIF dopamine, respectively. Dopamine inhibition of prolactin release is mediated by the dopamine 2 (D2) receptor. Alternative splicing results in a long and short form of the D2 receptor, and this allows coupling to different types of G-protein. When activated, the D2 receptor inhibits adenylyl cyclase.

Whether the complexity of the neurohormones and receptors involved in the neural control of GH and ACTH release is a consequence of evolutionary convergence of different regulatory systems that are not deleterious and are therefore retained or whether complexity has developed as a consequence of selective pressure to provide flexibility or increase the number of variables that can influence the two systems remains to be determined.

Clinical relevance All the hypothalamic neurohormones have been used extensively as tests of anterior pituitary function, or pituitary responsiveness. In addition, neurohormone agonists and antagonists have been deployed for a variety of diagnostic tests and therapeutic regimes. Thus, analogs of CRH-41 and urocortin have been developed with a view to their possible use in the treatment of depression, anxiety, anorexia nervosa, and stroke. The use of dopamine agonists, such as bromocriptine, cabergoline, and quinagolide, for the treatment of hyperprolactinemia and prolactin-secreting pituitary adenomata has been

mentioned previously. GnRH superactive agonists and antagonists are used for chemical castration, as an adjunct treatment of cancer of the breast and prostate gland, for fertility control, and for the treatment of infertility and precocious puberty. Somatostatin, or its potent synthetic analogs such as Octreotide, has been used in the treatment of GH-secreting pituitary adenomas that lead to acromegaly and also ectopic GH-secreting tumors, most commonly small-cell carcinomas of the lung or tumors of the gastrointestinal system. The action of Octreotide in treating GH-secreting tumors can be potentiated by dopamine agonists such as bromocriptine and cabergoline.

Somatostatin and its agonists are also effective in the treatment of pancreatitis. Orally active, nonpeptide mimetics of GHRP-6, such as MK-677, have been developed and these may have therapeutic value in the treatment of children of short stature and adult GH deficiency. GHRH, GHRP-6, and its mimetics are also being explored as useful agents for the treatment of metabolic deficiencies that occur in aging.

Teleology of Neurohormonal Control

The hypothalamic-pituitary axis illustrates the remarkable economy of physiological systems. First, and perhaps most impressive, are the hypophyseal portal vessels, which, by transporting the neurohormones from the hypothalamus to the pituitary gland, undiluted by mixture in the systemic circulation, ensure that hypothalamic neurohormones released in very small amounts from the hypothalamus reach the pituitary gland at concentrations several orders of magnitude greater than in the systemic circulation and therefore sufficient to exert their effects. The corollary of this is that relatively little neurohormone needs to be released to exert its effect and that therefore only a small amount of new neurohormone needs to be synthesized. The metabolic economy of the hypophyseal portal system is brought into sharp relief by the fact that the hypothalamic concentration and total content of the hypothalamic-anterior pituitary regulatory neurohormones are three or more orders of magnitude lower than those of the neurohypophyseal nonapeptides AVP and oxytocin, which reach their peripheral targets by the systemic circulation.

Second, the transport of neurohormones at effective concentrations by the hypophyseal portal vessels also protects the body from the potential adverse effects of the high concentrations of neurohormones necessary to stimulate or inhibit pituitary hormone secretion. Thus, for example, the high portal blood concentrations of somatostatin may, in the systemic

circulation, have adverse effects on the gut and on insulin secretion by the pancreatic islets. Similarly, as shown by Fink and associates, the portal plasma concentrations of ANP that inhibit ACTH secretion would, in the systemic circulation, cause a lethal drop in blood pressure.

Third, neurohormones in the hypothalamo-adenohypophyseal system, by also serving as chemical messengers in several related systems or mechanisms, may serve to orchestrate appropriate physiological responses. Thus, for example, somatostatin, in addition to inhibiting GH secretion is also secreted by pancreatic islets and inhibits the secretion of insulin, glucagon, and a range of gut peptides. As mentioned earlier, CRH-41 is present in higher brain centers and in the periphery, and it has been implicated in stress-related behaviors, cardiovascular control, and the synchronization of the endocrine, autonomic, and immunological components of the stress response.

The Hypothalamo-Neurohypophyseal System

Principles and Overview

The neural lobe is the site of release of the nonapeptides oxytocin and AVP into the systemic circulation. Presumably because a considerable distance removes the target cells of these peptides from their site of release in the neural lobe and because there is massive dilution in the systemic circulation, the rate and the amount of synthesis of oxytocin and AVP and their content in the hypothalamus are about three orders of magnitude greater than that of neurohormones concerned in anterior pituitary control. This fact, together with their synthesis in discrete hypothalamic nuclei, their ease of assay, and that both nonapeptides contain disulfide bridges that allow the incorporation of the radioactive tracer [³⁵S]-cysteine, contributed to four important landmarks in neuroendocrinology. First, oxytocin and AVP were the first of the hypothalamic neurohormones to be sequenced (by Du Vigneaud and colleagues). Second, the glycoprotein components of their precursor proteins led to their conspicuous histochemical staining and thereby to the concept of neurosecretion (the Scharrers), a term applied to neurons whose main purpose seemed to be to secrete neurohormones rather than transmit signals by propagated action potentials. Third, the fact that both peptides have disulfide bridges and that synthesis involves the incorporation of cysteine, which can be labeled with the relatively high-energy radionuclide ³⁵S, made them excellent models for the first studies of neuropeptide synthesis and transport (first shown by Sachs and associates). Fourth,

oxytocin- and AVP-containing neurons were the first neuroendocrine neurons from which electrophysiological recordings were made (by J. Green and B. Cross in 1959).

The concept of neurosecretion was soon discarded because it was shown that the magnocellular neurons are no different from others – they propagate action potentials and release neurohormones or neurotransmitters. In fact, oxytocin- and AVP-containing neurons facilitate electrophysiological recording because they are large and because their axons terminate in the surgically accessible neural lobe. This makes it relatively easy to locate and verify by antidromic stimulation the identity of the neurons and record from them. Furthermore, the electrophysiological activity of the hypothalamic magnocellular neurons can be correlated with the secretion of AVP and oxytocin.

Finally, because the neural lobe is largely made up of nerve terminals, it proved to be a useful model for the study of exocytosis and stimulus-secretion coupling, the coupling between the cascade of ion fluxes through membrane channels (membrane depolarization) triggered by action potentials and the calcium-dependent release of neurohormones or neurotransmitters. Neurohormones, like all other known neurotransmitters and peptide and protein hormones, are packaged in secretory vesicles (Figure 6), which are released in packets or quanta.

Function

AVP (or the antidiuretic hormone) is concerned mainly with the control of body water. As its name implies, AVP also induces vasoconstriction and thereby can increase blood pressure, although this mechanism usually becomes operational only after a substantial loss of blood volume. AVP cells of the SON and PVN respond to osmotic stimuli. An increase in plasma osmolality triggers the release of AVP, which increases water reuptake in the nephron, which as a consequence causes an overall increase in body water with a fall in plasma osmolality. This is a perfect example of a homeostatic regulatory mechanism. In addition to its role in osmoregulation, AVP synthesized in the smaller (parvocellular) neurons of the PVN acts synergistically with CRH-41 to release ACTH.

Oxytocin, concerned mainly with milk ejection during lactation and parturition (the birth process), provides the perfect example of the role of neurohormones in neuroendocrine reflexes. Thus, oxytocin is the neurohormonal component of the milk-ejection reflex whereby suckling at the nipple of lactating mothers triggers volleys of impulses that travel through the mammary nerves to the spinal cord and,

by way of a multisynaptic pathway, reach the hypothalamus where they trigger the release of oxytocin. Oxytocin transported by the systemic circulation stimulates the contraction of the myoepithelial cells of the breast, resulting in milk ejection. During parturition, oxytocin coordinates and reinforces uterine contractions. That is, as uterine contractions force the head of the fetus against the cervix, volleys of impulses are triggered that ascend through multisynaptic pathways involving the pelvic nerves and the spinal cord to the hypothalamus to trigger the release of oxytocin, which acts on the smooth muscle cells of the uterus. This is a classical positive feedback system, which is terminated by expulsion of the fetus and placenta.

The Intermediate Lobe of the Pituitary Gland

Model for Posttranslational Processing

The major secretion of the intermediate lobe of the pituitary gland is α -melanocyte-stimulating hormone (α -MSH), a 13-amino-acid-residue peptide that, together with ACTH and β -endorphin, is derived from the precursor proopiomelanocortin (POMC). In addition to α -MSH, the pars intermedia also contains other derivatives of POMC – β -MSH, γ -MSH, corticotropin-like intermediate lobe peptide (CLIP), and β -endorphin – which together with the ACTH make up the melanocortins. The fact that in the pars distalis ACTH is the major hormone derived from posttranslational processing of POMC, whereas in the pars intermedia α -MSH is the major active hormonal product of POMC processing, reflects the presence of different enzymatic processing pathways in the two parts of the gland. The release of α -MSH is inhibited by dopaminergic neurons that originate in the arcuate nucleus and reach the intermediate lobe by way of the neural stalk. Humans are conspicuous among mammals in that the pars intermedia is not defined as a separate lobe of the human pituitary gland.

Melanocortins

Although they are all derived from POMC, melanocortins have diverse physiological functions. α -MSH, first thought to stimulate the growth of melanocytes and pigment formation (melanogenesis), is also involved in fever, inflammation, and the immune response. Indeed, several of the melanocortins, including ACTH, affect cytokine-induced effects on thymocytes, T and B lymphocytes, and neutrophils. The actions of the melanocortins are mediated by five melanocortin receptor subtypes (MC1–5). Although

all the melanocortin receptors are seven-transmembrane G-protein-coupled, the tissue distribution of the five receptors is quite distinct. Thus, the MC1 is located on melanocytes and mediates MSH-stimulated melanocyte proliferation and melanogenesis, while the MC2 receptor is located in the adrenal cortex, where it mediates the ACTH-induced secretion of glucocorticoids and mineralocorticoids. The MC3 and MC4 receptors are both located in the brain; the function of MC3 is unknown, but MC4 is involved, together with leptin (a protein produced by adipocytes) and neuropeptide Y, in the regulation of body weight. Studies on mutant *ob/ob* mice show that the action of leptin in regulating body weight is mediated, at least in part, by hypothalamic melanocortin activation, which results in decreased food intake. The importance of hypothalamic melanocortin activity for moderating food intake is illustrated by the agouti peptide, which is a high-affinity antagonist for the MC1 receptor and induces obesity in the mouse. The MC4 receptor is also involved in grooming behavior. The MC5 receptor, whose function remains unknown, is widely distributed in body organs, including the spleen, thymus, skin, and bone marrow. Cutaneous pigmentation is a function of the MC1 receptor, and MC1 gene variants may predispose to red hair and light skin color, which may make the individual susceptible to melanoma.

Pineal Gland: Melatonin and Photoperiodic Control of Circadian Rhythms

The pineal gland is a circumventricular organ (Figure 1) that secretes melatonin into the circulation and plays an important role in the photoperiodic control of reproduction in seasonal breeding animals. The gland deserves special mention here because it reinforces the principles of neuroendocrine control. Philosophers (e.g., Descartes, who called this the seat of the soul) and scientists have long been intrigued by the pineal. The secretion of melatonin is exquisitely sensitive to light. Pinealocytes in submammalian species are photoreceptors, and the gland offers an excellent experimental model for studies of the transduction of light into nerve impulses and neurohormone secretion.

The outer segment (sensory pole) of the pinealocyte in fish, amphibia, and reptiles has all the ultrastructural characteristics of a true photoreceptor, but these features are only vestigial in mammals and intermediate forms exist in birds. In fish, amphibia, and reptiles, the effector pole of the pinealocyte synapses with secondary pineal neurons that give rise to the pineal tract, which transmits signals to the CNS.

In birds and mammals, however, pinealocytes secrete melatonin directly into the circulation (or cerebrospinal fluid) in a neuroendocrine manner.

Melatonin, a derivative of serotonin, is synthesized within pinealocytes in two steps. First, serotonin is converted by *N*-acetyl-transferase (NAT) to *N*-acetyl serotonin, which is then converted to melatonin by hydroxyindole-*O*-methyltransferase. Because little if any melatonin is stored, the rate of melatonin secretion is tightly linked to its synthesis, which depends on NAT action, which in turn depends on norepinephrine release from the dense sympathetic innervation of the gland. In mammals, the control of melatonin secretion by light is mediated by a multisynaptic pathway that starts in the retina of the eye and successively involves synapses in the suprachiasmatic nuclei, the PVN, the intermediolateral column of the spinal cord, and the neurons of the superior cervical ganglion of the sympathetic nervous system. Sympathetic terminals in the pineal gland release norepinephrine, which stimulates melatonin secretion by an action on adrenoreceptors on pinealocytes. cAMP seems to be the main intracellular second messenger that mediates the action of norepinephrine in this system. The main point of regulation seems to be NAT, which, depending on the species, can be affected at the level of NAT gene expression as well by posttranslational modifications that alter the activity of the enzyme.

The secretion of melatonin starts with the onset of the dark period (night) and stops with the onset of the light period (day). The secretion of melatonin during the dark period is stopped abruptly by exposure to light. In blind people, the secretion of melatonin takes on the typical 25-h free-running period. Taken together, these and other data suggest that the secretion of melatonin is predominantly controlled by light exposure superimposed on the intrinsic rhythm of the major neural clock, the suprachiasmatic nuclei.

An interaction between melatonin and the hypothalamic-pituitary-adrenal stress response system has been suggested; indeed, melatonin has been implicated in glucocorticoid receptor-induced gene expression. However, the precise role of melatonin in the circadian rhythm of ACTH and adrenal corticosteroids, and in the stress response, has yet to be established. This applies equally to the long-researched but unanswered questions as to whether melatonin is a hypnotic or sedative and whether it can resynchronize circadian rhythms that have been disrupted by rapidly crossing time zones (jet lag). Melatonin is a powerful antioxidant, which may explain some of its alleged beneficial effects with respect to aging. So far, the most robust evidence regarding the function of melatonin in mammals relates to its inhibitory actions with respect to reproduction, especially in

seasonal breeding animals such as the wallaby, hamster, vole, and sheep.

What is well established is that the suprachiasmatic nuclei constitute the central generator of circadian rhythms of the body, with one notable exception – the daily anticipation of a meal. That is, rats in which the suprachiasmatic nuclei have been lesioned are still able to anticipate one meal per day. This anticipation is associated with an increase in activity, core body temperature, and plasma corticosterone concentrations that occur 2–4 h before access to the meal. The precise nature and location of the feeding-entrained oscillator that presumably determines the daily rhythm of feeding anticipation have yet to be established. However, studies with *c-Fos* (early immediate gene) activation have implicated the nucleus accumbens and the limbic system. The relative importance of the pineal gland and its precise role in the photoperiodic control of circadian rhythms also wait to be determined. With the discovery of genes that regulate circadian rhythms and melatonin synthesis, the prospects of defining what is likely to be a remarkably elegant and robust molecular control system seem excellent.

Hormonal Effects on the Nervous System

The steroid and thyroid hormones, the secretions of the three major pituitary target organs, exert powerful effects on the brain. These effects may be classified in terms of (1) feedback actions, (2) brain differentiation and neural plasticity, (3) neurotransmission, and (4) membranes and ion channels. Feedback actions of the corticosteroids on the brain and pituitary gland are discussed in detail elsewhere. Many entries also deal with the specific effects of corticosteroids on brain that are mediated by corticosteroid receptors, but that are not necessarily related to the feedback control of ACTH release. For information on the actions of steroids on brain differentiation, neurotransmission, cell membranes, and ion channels, the reader is referred to the Bibliography.

Psychoneuroendocrinology

The recognition that the secretion of pituitary hormones reflects the activity of hypothalamic neurons, which in turn reflects neurotransmitter activity in the brain, provides the basis for the use of pituitary hormone secretion as a marker of disordered central neurotransmission that may underlie or be associated with mental disorders. The development of this discipline, psychoneuroendocrinology, has been impeded by our lack of fundamental knowledge about the precise neurotransmitter regulation of hypothalamic

neurons that regulate the anterior pituitary gland. Nonetheless, several robust findings have been made and these provide important clues for further research that might optimally be carried out in conjunction with human genetics and sophisticated brain imaging.

For example, it has long been known that plasma cortisol concentrations are abnormally high in patients with psychosis, especially severe depression. Furthermore, as shown by the groundbreaking work of Carroll and Rubin and their associates, in many psychotic patients it is not possible to suppress these high cortisol concentrations by injecting a glucocorticoid agonist such as dexamethasone (the dexamethasone suppression test). Although it cannot accurately discriminate among the different types of psychoses, the failure of dexamethasone to suppress cortisol levels provides robust biological evidence that a patient is suffering from a severe psychosis. The inability of dexamethasone to suppress cortisol levels in many patients with depressive psychosis points to a significant abnormality in the regulatory mechanism for ACTH release. The elucidation of the precise nature of this abnormality may help explain the central neurotransmitter dysfunction that leads to severe depression or other psychosis.

The growth hormone and prolactin responses to pharmacological challenge are also abnormal in certain psychotic states. In anorexia nervosa, for example, a life-threatening condition that occurs predominantly in young women, the normal GH surge that can be induced by the infusion of L-tryptophan, the precursor for serotonin synthesis, is completely absent. This cannot simply be attributed to a lack of food intake because the GH response to L-tryptophan infusion is enhanced, rather than suppressed, in women of a similar age who have been placed on a low-calorie diet. Again the precise explanation for this phenomenon, first shown by Guy Goodwin and associates, is not established, but points to an abnormality in central serotonin function that may underlie or be associated with anorexia nervosa.

The advantages of the psychoneuroendocrine investigation of mental disorders are that it is relatively inexpensive, only mildly invasive, and can be carried out in severely ill patients. Its power will depend on further fundamental research that may enable us to interpret accurately the neuroendocrine responses to pharmacological challenge.

Development of the Dentate Gyrus

Stress Effects on Neurogenesis

Adrenal Steroids Affect Neurogenesis through NMDA Receptors

Functional Implications of Stress Effects on Neurogenesis

Glossary

Bromo-deoxyuridine (BrdU) labeling

A nonradioactive method for labeling proliferating cells and their progeny. BrdU is a thymidine analog that is incorporated into cells that are in the DNA synthetic phase of the cell cycle. BrdU incorporation can be visualized using immunocytochemical methods and can be combined with stereological analyses to estimate the total numbers of new cells generated at a given time. Short survival times (e.g., 2 h) can be used to label proliferating cells. When combined with the use of immunohistological markers, longer survival times (e.g., several weeks) can be used to determine the cellular phenotype of the newly generated cells.

Dentate gyrus

A brain region that is part of the hippocampal formation. It consists of the following three major components: (1) the granule cell layer, densely packed with granule cell bodies; (2) the hilus, a region that contains the granule cell axons (mossy fibers), interneurons, and progenitor cells; and (3) the molecular layer, a region that contains the granule cell dendritic trees and interneurons.

Neurogenesis

The process of forming a new neuron. Neurogenesis involves the proliferation of neuronal progenitors and the subsequent differentiation of these cells into neurons.

[³H]Thymidine autoradiography

A method that labels proliferating cells and their progeny with radio-labeled thymidine, a molecule that is incorporated into cells that are in S phase. Cells that have incorporated [³H]thymidine can be visualized with autoradiography. However, because [³H]

thymidine autoradiography allows the detection only of labeled cells in the top 3 μm of a section, this technique cannot be used for stereological analyses.

Most neurons in the mammalian brain are produced during the embryonic period. In contrast, the granule cell population of the dentate gyrus of the hippocampal formation is produced during an extended period that begins during gestation and continues well into adulthood. Previously, it was shown that the production of new granule neurons is suppressed by stress. Taken together, these observations suggest that stressful experiences during postnatal development and adulthood have the potential to significantly alter both the structure and function of the hippocampal formation.

Development of the Dentate Gyrus

In most regions of the mammalian brain, the majority of neurons are produced during a discrete part of the embryonic period. In contrast, granule neurons in the dentate gyrus of the hippocampal formation are produced primarily during the postnatal period and throughout adulthood in mammalian species ranging from rodents to primates, including humans. During the embryonic period, the first granule neurons arise from progenitor cells located in the wall of the lateral ventricle that migrate across the hippocampal rudiment to reside in the developing granule cell layer (Figure 1a). A subpopulation of these progenitor cells does not undergo final division, is maintained in the hilus and subgranular zone of the dentate gyrus, and continues to give rise to new granule neurons. In the rodent, the majority of neurons in the dentate gyrus are produced during the first 2 postnatal weeks from this secondary proliferative zone; cells in the hilus and subgranular zone divide, migrate along radial glial fibers, and ultimately reside in the granule cell layer (Figure 1b). In addition, some granule neurons are also produced from cells within the granule cell layer during this period. Following the second postnatal week, cell proliferation and migration decrease and the granule cell layer is formed. In the primate, the formation of the granule cell layer occurs during the prenatal period, but the production of new granule neurons continues postnatally as well.

In both rodents and primates, new neurons are produced throughout adulthood from progenitor cells

Figure 1 Development of granule cells. a, Embryonic period; b, late embryonic period. During the embryonic period, the first granule neurons arise from progenitor cells located in the wall of the lateral ventricle that migrate across the hippocampal rudiment to reside in the developing granule cell layer. During the late embryonic period and early postnatal development, granule cell precursors in the hilus divide and migrate to the granule cell layer. At the same time, precursor cells in the lateral ventricle continue to migrate into the dentate gyrus. The stippled area represents dentate gyrus neuroepithelium of the lateral ventricle (LV); solid circles represent migrating granule neuron precursors; open circles represent postmitotic immature granule neurons.

located in the hilus and subgranular zone (**Figure 2**). Studies using [^3H]thymidine or bromodeoxyuridine (BrdU) molecules, which are incorporated by cells during S phase, and various histological markers of cell phenotype have revealed that cells divide, migrate, extend axons, become incorporated into the granule cell layer, and ultimately express the morphological and biochemical characteristics of mature granule neurons. Although the numbers of new cells produced are much fewer than those observed during development, stereological studies have demonstrated that several thousand new cells are produced each day in the adult rodent brain. Because the majority of neurons in the dentate gyrus are produced postnatally, this brain region is particularly sensitive to changes in the environment during both postnatal development and adulthood compared to other brain regions. Thus, factors that regulate the production of granule neurons are capable of exerting significant effects on both the structure and the function of the hippocampal

formation, which may extend throughout the life of the organism. The remaining part of this article focuses on the regulation of granule neuron production by stress, the factors likely to mediate this regulation, and the possible functional implications of stress-induced changes in postnatal neuron production.

Stress Effects on Neurogenesis

During the first 2 postnatal weeks, termed the stress hyporesponsive period, rat pups exhibit a diminished response to most stressors that are known to increase circulating levels of adrenal steroids in adulthood. However, male rat pups do exhibit an increase in circulating corticosterone levels following acute exposure to the odor of an unfamiliar adult male (adult males are a natural predator of rat pups). Using this paradigm, it has been shown that a single exposure to the odors of an unfamiliar adult male during the stress hyporesponsive period results in a significant

Figure 2 Production of new neurons. a, Progenitor cells; b, incorporation into granule cells. In both rodents and primates, new neurons are produced throughout adulthood from progenitor cells located in the hilus and subgranular zone (sgz). Studies using [^3H]thymidine or bromodeoxyuridine, both of which are incorporated by cells during S phase, and various histological markers of cell phenotype have revealed that these cells become incorporated into the granule cell layer (gcl) and ultimately express the morphological and biochemical characteristics of mature granule neurons.

decrease in the proliferation of granule cell precursors in the developing dentate gyrus 24 h following exposure.

Acute stressful experiences also decrease the number of new granule neurons produced during adulthood in a number of different species, including rats, tree shrews (animals considered to be phylogenetically between insectivores and primates), and marmosets. In adult rats, exposure to the odors of natural predators, such as foxes or weasels, elicits a stress response characterized by increased serum corticosterone levels and a characteristic electrophysiological response in the dentate gyrus. A single brief exposure to trimethyl thiazoline, a component of fox feces, rapidly suppresses the proliferation of cells in the dentate gyrus.

Similar observations have been made in studies that have examined the effect of social stress in nonrodent species. In tree shrews, the introduction of two adult same-sex conspecifics immediately results in the establishment of an enduring dominant-subordinate relationship. During this time, the subordinate exhibits a robust stress response characterized by elevated cortisol levels, increased heart rate, hypoactivity, and vigilance. Although able to recover physically on removal from the presence of the dominant, the subordinate exhibits an immediate stress response during subsequent encounters with the dominant. A single

brief exposure to a dominant animal, without physical contact, results in a rapid decrease in the number of new cells produced in the dentate gyrus of subordinate tree shrews compared to control animals. Likewise, studies of marmosets using a resident intruder paradigm, a model of psychosocial stress similar to the dominant-subordinate paradigm used with tree shrews, have yielded similar results. In this paradigm, a male marmoset is introduced into the cage of another male. Immediately after being placed in the cage, the intruder exhibits a stress response characterized by elevated mean arterial pressure and a dramatically increased heart rate. A single brief exposure to a psychosocial stress in the resident-intruder paradigm results in a rapid decrease in the number of new granule neurons produced in the dentate gyrus compared to naïve control animals.

In addition to exerting an acute impact on granule cell production, stress has also been shown to produce prolonged suppression of this process with repeated exposure. It has been demonstrated that 28 days of exposure to a dominant animal for 1 h each day results in a chronic increase in cortisol levels in adult tree shrews. Furthermore, exposure to chronic stress using this paradigm also results in a decrease in new cell production in the dentate gyrus, which is associated with a decrease in the total volume of the granule cell layer.

Adrenal Steroids Affect Neurogenesis through NMDA Receptors

Although the factors that mediate the stress-induced suppression of granule cell production remain unknown, adrenal steroids are likely to play a significant role in this effect. Several lines of evidence have indicated that adrenal steroids naturally regulate the production of hippocampal granule neurons. First, throughout life, a negative correlation between circulating adrenal steroid levels and the rate of granule neuron production exists. During the late embryonic period, adrenal steroid levels are high and few granule cells are produced. Following parturition, basal levels of glucocorticoids are low during the stress hyporesponsive period. This 2-week period is characterized by a diminished response to stress and maximal rates of neurogenesis. By the third postnatal week and into adulthood, circulating adrenal steroid levels are relatively high and granule production is diminished compared to the levels observed during development. With aging, the levels of glucocorticoids are elevated further and the rate of granule cell production becomes minimal.

Consistent with these natural observations, several studies have demonstrated that the production of neurons can be altered by the experimental manipulation of circulating adrenal steroid levels both during development and adulthood. During the stress hyporesponsive period, the administration of corticosterone results in a significant decrease in the number of granule neurons produced. Similar suppressive effects of adrenal steroids on the proliferation of granule cell precursors have been observed in adulthood as well. The treatment of adult rats with corticosterone results in a decrease in the production of new cells, whereas the removal of adrenal steroids by adrenalectomy results in a rapid increase in the number of new cells produced and, ultimately, in the number of new granule neurons. Despite the dramatic effects of hormone manipulations on cell proliferation in the dentate gyrus, very few granule cell precursors express adrenal steroid receptors, suggesting that adrenal steroids influence neurogenesis indirectly.

In addition to increasing circulating adrenal steroid levels, stressful experiences stimulate hippocampal glutamate release and alter the expression of the NMDA subtype of glutamate receptor in the hippocampal formation. Several lines of evidence suggest that adrenal steroids affect cell proliferation in the dentate gyrus via excitatory input. First, the timing of perforant path development and increased expression of NMDA receptors in the developing dentate gyrus coincides with an observed decrease in granule neuron production. Second, experimental manipulation

of NMDA receptor activation during development or adulthood results in rapid changes in the numbers of new granule neurons. The administration of NMDA receptor antagonists increases the proliferation of granule cell precursors and the production of new granule cells during the early postnatal period and in adulthood in rats and tree shrews. It is likely that these effects are mediated by the perforant pathway, inputs that can involve NMDA receptor activation, because lesion of the entorhinal cortex enhances cell proliferation in the dentate gyrus in adulthood.

The regulation of granule cell production by adrenal steroids and NMDA receptor activation occur via a common pathway. Treatment with corticosterone and MK801 during adulthood results in an increase in cell proliferation that is similar to that observed with MK801 treatment alone. Conversely, adrenalectomized rats that are treated with NMDA demonstrate numbers of proliferating cells that are similar to animals treated with NMDA alone; both groups demonstrate a significant decrease in the numbers of proliferating cells compared to control animals. Collectively, these results indicate that adrenal steroids and NMDA receptor activation decrease cell proliferation via a common pathway. In addition, these results indicate that NMDA receptor activation exerts a more proximal effect on cell proliferation, as evidenced by the fact that the experimental manipulation of NMDA receptor activation can block the effects of corticosterone.

Although the mechanism by which adrenal steroids and NMDA receptor activation suppress cell proliferation is not known, it is possible that these factors initiate a cascade of events that result in a lengthening of the cell cycle. *In vitro* studies in nonneuronal systems have shown that glucocorticoids are capable of lengthening the G1 phase or G2/M phases of the cell cycle. Alternatively, these factors may induce changes that prevent precursor cells from progressing through the cell cycle. *In vitro* studies have also demonstrated that glucocorticoids can reversibly halt the progression of the cell cycle in nonneuronal systems. If adrenal steroids do in fact inhibit progenitor cells from dividing, the removal of adrenal steroids may result in the disinhibition of cells that are normally prevented from progressing through the cell cycle. Such an effect could account for the speed and magnitude of the increases in the number of cells in S phase following the removal of adrenal steroids.

Functional Implications of Stress Effects on Neurogenesis

The functional implications of the stress-induced suppression of neurogenesis are not known. However, the

suppression of granule cell production during a time when the majority of granule neurons are produced is likely to have a significant effect on the structure of the adult hippocampal formation. The hippocampal formation has been implicated in learning and memory, raising the possibility that decreases in the production of granule neurons during development may have a negative impact on learning and memory in adulthood. Although there is some evidence to support the idea that stressful experience during development is correlated with impaired cognitive function, an involvement of stress-induced changes in granule neuron production has not yet been investigated.

Although the exact functional significance of adult-generated neurons is not known, evidence suggests a relationship between these new cells and hippocampal-dependent learning. Specifically, the survival of adult-generated cells appears to depend on learning hippocampal-dependent tasks at a critical time after their production. Taken together with the observation that stress suppresses the production of granule neurons, the finding that learning enhances the number of granule neurons suggests that stress-induced changes in neurogenesis may have a significant impact on learning. It is important to note that functional changes are not likely to be immediately evident. New cells require time to differentiate and become incorporated into functional circuitry. Thus, the period following stress-induced changes in cell proliferation is most likely to be functionally relevant. In addition, it is important to note that the functional changes attributable to acute changes in cell production are not likely to be of an observable magnitude. For this reason, the impact of stress-induced changes in neuron production is most likely to be of interest when considering conditions of chronic stress. Thus, although previous studies have demonstrated enhancements in learning as a result of conditions of acute stress, the mechanisms that underlie these effects are likely to involve processes other than changes in neuron production, such as changes in synaptic efficacy.

Several studies have demonstrated that chronic stress or corticosterone treatment exerts a significant impact on hippocampal-dependent learning. In addition, later studies have demonstrated that a stress-induced impairment of spatial learning on different tasks can be observed with both a shorter and a longer duration of stress; 8 days of psychosocial stress result in impaired performance on the hole board spatial discrimination task, and exposure to 6 months of psychosocial stress results in impaired performance on the Morris water maze spatial learning task. The stress-induced impairment observed is not permanent; rats that were tested on the radial arm maze 18 days

following the termination of stress performed comparably to control rats. This observation is consistent with a possible involvement of adult-generated cells. If adult-generated cells are indeed necessary for normal performance on this task, an impairment may only persist as long as the production of these cells is altered. Once the stress-induced decrease is no longer present, we expect to observe normal levels of performance. However, stress-induced impairments during the early postnatal period, when the granule cell layer is forming, may have lasting effects.

In general, the degree to which the structure of the adult brain can be altered by experience is limited by the fact that neurons in most brain regions are produced during a discrete period of early embryonic development. Thus, the postnatal production of neurons in the dentate gyrus presents an unusual situation in which the experience of an organism may exert dramatic and potentially long-lasting effects on the structure and function of this brain region.

Emotion Regulation

Emotion Dysregulation

Glossary

<i>Amygdala</i>	An almond-shaped cluster of inter-related nuclei and associated cortex in the anterior medial temporal lobe.
<i>Arousal</i>	A dimension of emotion that varies from calm to excitement and predicts behavioral activity level.
<i>Blood-oxygen level-dependent (BOLD) signal</i>	T2*-weighted signal in functional magnetic resonance imaging (fMRI) that reflects hemodynamic changes in regional perfusion evoked by neural activity.
<i>Functional magnetic resonance imaging (fMRI)</i>	A non-invasive technique with good spatial resolution that detects changes in regional blood flow associated with neural activity.
<i>Interoception</i>	A representation of visceral activity; the afferent limb of homeostatic neural control of bodily organs.
<i>Magnetoencephalography (MEG)</i>	A non-invasive technique with high temporal resolution that detects the changing magnetic fields associated with neural activity.
<i>Valence</i>	A dimension of emotion that varies from unpleasant (negative) to pleasant (positive) to reflect motivational value.

Emotion

Emotion is central to our everyday human experience. Emotional events or objects within our environment are assigned value, bias our attention, and enhance our subsequent memory. Neuroimaging techniques, perhaps more than other approaches, have led to a growing awareness that emotion, unlike many other psychological functions, is relatively unencapsulated and interacts with and influences multiple

other areas of functioning. In addition to effects on attention, perception, memory, and learning, emotion also forms the backbone of our social relationships and is an important component of empathetic understanding of others. Emotional cues also act as powerful reinforcers, have a marked influence on our thoughts and reasoning, and serve to bias our ongoing behavior. Although emotions come in many flavors that may equally serve to bias multiple psychological functions, much of the contemporary research on emotional neuroscience has focused on the processing of fear. For the purposes of this article, we follow this focus, which also accords with an emphasis on stress responses.

Consistent with a broad role in human functioning are the wide-ranging manifestations associated with disorders of emotion regulation. Emotion disequilibrium underlies not just anxiety and stress-related illness but the entire range of mental disorders and acts as the common denominator in much of human unhappiness. This article reviews the contributions of neuroimaging studies to our developing understanding of the neurobiology of human emotion. One particular aim is to highlight how emotion interacts with and influences other areas of cognition and to illustrate how an understanding of the mechanisms underlying these interactions can enable a greater understanding of stress-related disorders.

Definition of Emotion

Differences in definition can lead to markedly different conceptualizations of emotion and underlie seemingly contradictory theories of emotion in the literature. A prevalent view conceptualizes emotion as a transient perturbation in an organism's functioning evoked by a triggering (i.e., emotive) stimulus (either external or internal). Most accounts of emotion also subscribe to a multicomponential description with physiological arousal, motor expression, and subjective feelings forming the reaction triad of emotion. However, the extent to which changes in these various components are necessary and sufficient to define an episode as emotional is more controversial. For the purposes of this article, we use the following definition: emotions are transient events, produced in response to external or internal events of significance to the individual; they are typically characterized by attention to the evoking stimulus and changes in neurophysiological arousal, motor behavior, and subjective feeling state that engender a subsequent biasing of behavior.

Emotion Perception and Attention

Implicit within this definition is that events of significance to the individual (emotive stimuli) are susceptible to preferential perceptual processing. One mechanism through which this is achieved is through the emotional biasing of attentional processes. This is illustrated in behavioral studies using visual search paradigms, in which target items are discriminated from an array containing a variable number of distracter items. Emotionally valenced items or objects are indeed identified more rapidly than nonemotional items. Furthermore, in spatial tasks, the presentation of an emotional cue on one side of the visual space increases the speed of identification of nonemotional stimuli subsequently presented on the same side (i.e., attention is drawn to the location of the preceding emotive stimulus). Neuroimaging studies investigating the neural basis of this emotional capture of attention in spatial orientation tasks show that it is correlated with activity in regions of the frontal and parietal cortices as well as the lateral orbitofrontal cortex.

Evidence from patient studies, neuroimaging, and electroencephalography suggests that even unattended emotional stimuli are more likely to enter awareness, suggesting further mechanisms through which emotional stimuli influence perception. Neuroimaging studies continue to delineate the brain mechanisms through which unattended emotional stimuli gain enhanced access to awareness. One influential hypothesis suggests that the emotional salience of a stimulus is rapidly detected by the amygdala after cursory representational processing. The amygdala subsequently facilitates attention and perception via projections to the sensory cortices to enable more detailed sensory processing. Convergent anatomical studies suggest that this is mediated by both direct and indirect amygdala influences on sensory cortices; reciprocal direct connections exist between the amygdala and sensory cortices, and a projection from the central nucleus of the amygdala to the cholinergic nucleus basalis of Meynert enables indirect ascending cholinergic neuromodulatory influences to be exerted on the same cortical regions.

Functional neuroimaging studies have tested this hypothesis using visual backward-masking paradigms in which briefly presented visual targets are rendered invisible by subsequently presented stimuli. Unseen emotional stimuli, presented in this subliminal manner, can nevertheless still evoke neural responses in the amygdala, compared to nonemotional (neutral) stimuli. Moreover, masked presentations of face stimuli portraying fearful (vs. neutral) facial expressions enhances activation within the fusiform cortex (an

extra-striate visual area containing a region implicated as being specialized for processing faces). This activation of the fusiform face area (FFA) is predicted by the magnitude of amygdala activation. Further evidence that emotional processing in the amygdala may enhance activity within sensory cortex comes from the observation that patients with amygdala damage fail to show this enhancement of activity within the face-processing visual cortex when tested on the same paradigm. The presentation of fearful face cues has also been shown to enhance even early perceptual functions such as contrast sensitivity, which is consistent with the suggestion that the amygdala may modulate even activity within the primary visual cortex.

Preattentive processing of emotional stimuli indicates early representational discrimination between emotional and nonemotional events. Studies in humans using magnetoencephalography (MEG), a neuroimaging technique with high temporal resolution, showed discriminatory responses to emotional faces as early as 100–120 ms. This compares to characteristic face-related responses that occurs much later, at 170 ms. Electrophysiological studies in humans using intracranial electrodes also showed an early, 120- to 160-ms response to aversive stimuli. The early recognition of emotionally valenced stimuli accords with animal data suggesting that the amygdala may be activated by a rapid subcortical pathway. Neuroimaging studies in both normal and brain injury subjects highlight subcortical amygdala activation in humans. One study exploited two separate findings: (1) that low- and high-spatial frequency information is processed by separate visual neural pathways and (2) that coarse emotional cues are carried in low-frequency components. When subjects were presented low-frequency (blurred) face stimuli fearful (vs. neutral face stimuli), enhanced activity was seen in the amygdala, pulvinar nucleus of the thalamus, and superior colliculus, components of a proposed subcortical circuit (Figure 1). In contrast, the presentation of the same faces at high spatial frequency activated the cortical regions, including the fusiform (face-identity-specific) cortex. Implicit processing of emotional valence can be demonstrated in patients with damage to the primary visual cortex, who are not consciously aware of stimuli presented in their blind hemifield (i.e., blindsight). These patients show amygdala activation to fearful faces presented in their blind hemifield, illustrating the presence of the subcortical visual processing of emotion to the level of the amygdala.

Together these lesion and functional imaging studies provide mechanistic insight into the role of amygdala, through interactions with the sensory cortices, in facilitating enhanced attention and perception of

Figure 1 Neural activity in response to viewing facial expressions. a, High-spatial frequency information; b, low-spatial frequency information. High-spatial frequency images activated the fusiform cortex, specialized for the processing of facial identity. Fearful (vs. neutral) facial expressions activated the amygdala bilaterally (vertical arrows) with greater response to low-spatial frequency images. Low-spatial frequency fearful images also activated the posterior inferior thalamus bilaterally (diagonal arrows) and the superior colliculus on the right suggesting that low-spatial frequency images containing emotion information activate a subcortical pathway to the amygdala. Reprinted by permission from Macmillan Publishers Ltd: *Nature Neuroscience*; Vuilleumier, P., Armony, J. L., Driver, J., et al., Distinct spatial frequency sensitivities for processing faces and emotional expressions, **6**, 624–631, copyright (2003).

visually presented emotional stimuli. The preferential early processing of emotionally valenced material, illustrated most powerfully with fearful stimuli, sets up a primary bias in subsequent information processing that underpins the regulation of ongoing and prospective behavior.

Neuroscientific studies of human emotion have tended to focus on the visual processing of emotional facial expressions. Nevertheless, this visual communication of emotional state through changes in the facial musculature is only one part of a richer multi-modal vocabulary of affect. Information signaling emotional state is also conveyed by autonomic changes in the skin (leading to color change and sweating) and pupils, by posture and bodily movements, and by content and prosody of speech. Low-level auditory

processing of emotional signals are the primary source of emotional information in speech. The prioritized processing of emotional sounds, particularly non-speech intonations of emotional state (gasps, screams, etc.), is illustrated within the primary and accessory auditory cortices. As with the visual system, amygdalo-cortical interactions are implicated in enhanced auditory attention to emotive sounds. Moreover, specificity in emotional processing may cross sensory modalities, such that ventral insular regions implicated in disgust-processing may be activated by auditory and visual expressions of disgust as well as by disgusting stimuli.

A degree of regional specialization in human emotional processing is suggested from the convergence of lesion and neuroimaging studies. Acquired damage to the amygdala impairs the recognition and

behavioral experience of fear. Similarly, the neuroimaging literature emphasizes a predominant sensitivity of amygdala responses to threat and fear signals. As previously indicated, other studies implicate regions of insula and striatum in the selective processing of disgust. The impaired recognition of facial expressions of disgust was reported in a patient with damage to these regions, whereas the stimulation of the insula may evoke feelings of nausea or a perception of unpleasant tastes. These lines of evidence for specialized emotion-specific processing within different brain regions are generally circumscribed to fear/threat (amygdala), disgust (insula and striatum), and, to a lesser extent, sadness (subgenual cingulate activity). Many neuroimaging studies highlight a general sensitivity of amygdala responses to the emotional intensity of external emotional stimuli, for which threat is perhaps most arousing.

The insula cortex also appears to play a more complex role in emotion perception, apparently through relating perceptual information with interoceptive representations of bodily states. Thus, insula activity is engaged during the recognition and experience of disgust, sadness, happiness, and fear; during the learning and expression of threat; during the perception of noxious stimuli; and during the experience of phobic symptoms, hunger, and satiety; and even during explicit facial emotion categorization.

Memory and Learning

Emotion has a striking and well described impact on memory processes. Animal studies, particularly the work of LeDoux, highlight the central role of the amygdala in fear conditioning, a form of implicit memory. The same is true in humans, illustrated in many neuroimaging and lesion studies. Fear conditioning is a rapid form of learning that a stimulus is potentially harmful. If an adverse event (unconditioned stimulus, US; e.g., a painful shock) occurs after a relatively innocuous stimulus, the latter (the conditioned stimulus, CS) comes to predict the adverse event and will engender arousal responses associated with the presence of threat. Patients with bilateral amygdala damage do not acquire conditioned fear responses (autonomic or motor), despite having an intact explicit knowledge of the association between the CS and US. Functional neuroimaging studies also confirm the importance of the amygdala in fear conditioning (i.e., the learning of CS-US associations). However the role of the amygdala in the expression of threat responses is more time-limited and shows habituation. Consistent with animal data, neuroimaging studies also describe amygdala engagement in more general associative reinforcement learning,

including operant stimulus-reward learning and appetitive behavior.

In addition to simple associative responses, human memory is characterized by declarative richness in episodic and semantic memory. These domains of memory, typically supported both at encoding and recollection by activity within the hippocampus, are strongly modulated by emotional experience. Typically, emotional events and stimuli are remembered better than nonemotional occurrences. Animal studies highlight noradrenergic mechanisms enhancing amygdalo-hippocampal connectivity in preferential encoding of emotional objects. Brain-imaging studies in humans have gone much further, highlighting amygdala activation during encoding actually predicts the accuracy of subsequent declarative memory of positively or negatively valenced stimuli (Figure 2) and in delineating the functional architecture for mood-congruency effects (in which negative information is encoded and recalled to a greater extent when the subject is in a negative mood and, likewise, positive material is encoded and recalled to a greater extent in positive mood states). However, the role of the amygdala extends beyond encoding processes; it is also engaged during the retrieval of emotional items and contexts.

Interoception and Subjective Feeling States

Changes in bodily state, reflected in both physiological arousal and motor behavior, are obligatory defining characteristics of emotion. James and Lange, and more recently Damasio, argued that emotional feeling states must have their origin in the brain's representation of the bodily (arousal) state. Without changes in bodily arousal, there is no emotion. This peripheral account of emotion predicts that afferent feedback signals from muscles and viscera associated with physiological arousal are integral to emotional experience. These mechanisms have been illuminated in a number of neuroimaging experiments examining central representation and rerepresentation of autonomic arousal states and homeostatic sensations, such as temperature.

The role of the insula cortex in this context is particularly interesting. In a positron emission tomography (PET) study, activation within the viscerosensory mid-insula cortex correlated closely with the actual stimulus temperature, yet the subjective ratings of the perceived intensity or pleasantness of hot and cold stimuli correlated with activity in the right anterior insula and orbitofrontal cortex. This finding suggests a dissociation between a primary central representation of viscerosensory information, within

Figure 2 Level of activity within the amygdala (arrows) during the encoding of emotional images predicts whether a subject is subsequently able to recall emotional pictures (emotional Dm) but not neutral pictures (neutral Dm). Reprinted from *Neuron* 48, E. A. Phelps & J. E. LeDoux, Contributions of the amygdala to emotion processing: from animal models to human behavior, pp. 175–187, Copyright 2005, and adapted from *Neuron*, 42, F. Dolcos, K. S. LaBar & R. Cabeza, Interaction between the amygdala and the medial temporal lobe memory system predicts better memory for emotional events, pp. 855–863, Copyright (2004), with permission from Elsevier.

mid-insula, and subjective feelings of warmth or cold, represented in the right anterior insula and orbitofrontal cortex. A general role for these regions in the representation of emotional feelings is also supported by their activation observed during generated states of sadness and anger, anticipatory anxiety and pain, panic, disgust, sexual arousal, trustworthiness, and even subjective responses to music.

Behavioral and neuroimaging studies in patients with selective peripheral autonomic denervation (pure autonomic failure, PAF) lend further support to the importance of viscerosensory feedback to emotional feelings. These patients, who do not have autonomic (e.g., heart-rate or skin-conductance) changes in response to emotional stimuli or physiological stressors, show a subtle blunting of subjective emotional experience. In a fear conditioning study of PAF subjects and controls, both groups showed amygdala activity during the learning of threat (face stimuli, CS, were paired with an aversive blast of white noise, US). However, compared to controls, the right insula cortex showed attenuated responses to threat stimuli in the PAF patients, suggesting this region is sensitive to the presence and absence of autonomic responses generated during emotional processing. Moreover, when the threat stimuli were presented unconsciously (using backward masking), the same insula regions (including the right anterior insula) were sensitive to both the conscious awareness of emotion events and induced bodily arousal reactions. This study, particularly, suggests that the right insula is a neural substrate for the contextual integration of external emotional events with feeling states arising from bodily reactions.

The notion that subjective emotional feelings arise from central representations of bodily arousal states

predicts that people who are more aware of their bodily responses may experience more intense emotions and feelings. Investigations examining individual differences in interoceptive awareness suggest that patients with anxiety disorders are more attuned to bodily reactions such as their own heartbeat or stomach motility. One such interoceptive task was translated into a neuroimaging study. Subjects were played a series of notes, presented in groups of 10, either synchronously or out of phase with their own heartbeats (see [Figure 3a](#)). In half the trials, subjects had to judge the timing of their heartbeat in relation to the notes (the control condition was a detection of a rogue note in the sequence). When subjects focused interoceptively to the timing of their own heartbeat, there was enhanced activity in the somatomotor, insula, and cingulate cortices. However, only one region, the right anterior insula cortex, reflected a conscious awareness of internal bodily responses (i.e., how accurately subjects performed the interoceptive task). Significantly, activity in this region, and even the relative amount of right anterior gray matter here ([Figure 3b](#)), predicted day-to-day awareness of bodily reaction and the subjective experience of negative emotions, particularly anxiety symptoms across individuals. Together these studies suggest that the right anterior insula is a principal neural substrate supporting conscious emotional feelings arising from interoceptive information concerning bodily arousal state ([Figure 4](#)).

Social Interaction

A characteristic of our social interactions is an intuitive ability to understand other people's mental and

Figure 3 Interoceptive awareness (measured as accuracy on a heartbeat detection task). a, Association with increased neural activity in the right anterior insula/operculum; b, correlation with the gray matter volume of the right anterior insula region. Further subjects with greater interoceptive awareness also showed greater neural activity in this region during interoceptive trials. Activity in this region also correlated with anxiety scores, suggesting that emotional feeling states are supported by explicit interoceptive representations within right insula cortex. Reprinted by permission from Macmillan Publishers Ltd: *Nature Neuroscience*; Critchley, H. D., Wiens, S., Rotshtein, P., et al., Neural systems supporting interoceptive awareness, 7(2), 189–195, copyright (2004).

emotional states. Humans show a marked tendency to mimic one another's gesticulations, emotional facial expressions, and body postures, suggesting that this mirroring of activity mediates and facilitates emotional understanding among individuals. At a neural level, cells in monkey premotor cortex have been described

that respond to observing or performing the same motor actions. Corresponding human imaging studies of action observation also illustrate premotor cortical activity when observing the actions of others, and magnetoencephalography (MEG) studies report resynchronization in the primary motor cortex. Significantly,

Figure 4 A functional neuroanatomical modification of William James's (1884) model of emotional responses. Emotional stimuli (S) elicit automatic emotional responses (R) via thalamus–amygdala pathways (solid line arrows). This low-level processing occurs independently of conscious cognitive processing. Peripheral autonomic responses are fed back to the mid-insula and then are remapped to the right anterior insula where they interact with higher-level cognitive processing. Emotional feeling states therefore result from peripheral-central interaction in the right anterior insula. Reprinted from *Trends in Cognitive Sciences*, 6(8), J. S. Morris, How do you feel?, pp. 317–319, Copyright (2002), with permission from Elsevier.

these mirror activations are somatotopic with respect to the body part performing the action.

Accumulating evidence supports the extension of these action-perception mechanisms to emotions and feeling states. A common neural representation is proposed for the perception of actions and feelings in others and their experience in self. Thus, viewing emotional facial expressions in others activates automatically mirrored expressions on one's own face (surprisingly, even when the observed facial expressions are masked, hence unavailable to conscious awareness). Significantly, this automatic mimicking of emotional expressions also extends to autonomic expressions of emotional states such as pupil size in expressions of sadness. Neuroimaging studies show shared neural activation in the somatosensory cortex when a subject experienced or observed another being touched, right insula activity when a subject experienced disgusting odors or observed expressions of disgust, and the activation of a common matrix of regions when a subject experienced or observed pain. The imitation or observation of emotional facial expressions also activates a largely similar network of brain regions including the premotor areas that are critical for action representation. There is also selectivity; compared to nonemotional facial movements, emotional expressions activate the right frontal operculum and anterior insula, and regions such as the amygdala, striatum, and subgenual cingulate are differentially responsive when imitating happy or sad emotions.

Emotion Regulation

Understanding the adaptive mechanisms through which we can control the expression of our emotions is clinically and socially important. Unlearning established emotional reactions is difficult. Many studies have examined the modulation of previously learned emotional responses with experimental extinction; the repeated presentation of a previously CS without its associated US rapidly leads to a diminished emotional response. Nevertheless, the relationship between the two stimuli is not forgotten but inhibited and can be rapidly reinstated. Neuroimaging of extinction learning (or the inhibition of emotional responses) shows increased amygdala activity in early extinction; however, retention after a day was associated with activity in the subgenual anterior cingulate and ventromedial prefrontal cortices, which suggests a role for this region in the longer-term recall of extinction learning (Figure 5).

Emotional responses may also be regulated volitionally, using cognitive control or reappraisal. For example, an image of a woman crying may be interpreted as one of sadness, but, if the subject is then told that the picture was taken after her daughter's wedding, it may be reappraised as one of great joy. Neuroimaging studies of emotional reappraisal demonstrate an attenuation of activity in the amygdala associated with enhanced activity in the left middle frontal gyrus, suggesting that activity within the lateral

Figure 5 Regions activated in the extinction of conditioned fear. a, Ventromedial prefrontal cortex (arrow) showing less response to the conditioned stimulus (CS+) during acquisition; b, amygdala activation (arrow) in response to the CS+ during acquisition versus early extinction. During extinction training, ventromedial prefrontal cortex activity gradually increased, and the magnitude of this increase predicted the retention of extinction learning. Extinction training resulted in a reduction of amygdala activity in response to the CS+ and predicted the success of early extinction. Reprinted from *Neuron*, **48**, E. A. Phelps & J. E. LeDoux, Contributions of the amygdala to emotion processing: from animal models to human behavior, pp. 175–187, Copyright (2005), and adapted from *Neuron*, **43**, E. A. Phelps et al., Extinction learning in humans: role of the amygdala and vmPFC, pp. 897–905, Copyright (2004), with permission from Elsevier.

prefrontal cortex modulates emotional reactivity of the amygdala, possibly via connections to medial prefrontal cortex. Similar cognitive emotion-regulation techniques can powerfully diminish responses acquired through fear conditioning, and neuroimaging studies using this paradigm again show increased activity in the left middle frontal gyrus with cognitive control. Taken together, these studies suggest that cognitive emotion regulation and lower-level extinction learning recruit similar overlapping neural mechanisms for the regulation of the amygdala to control primary emotional responses.

Emotion Dysregulation

The wide-ranging influences of emotion on other psychological functions may also be seen in the variety of symptoms and presentations associated with emotional disorders. Posttraumatic stress disorder (PTSD), resulting from exposure to a highly traumatic emotional event and usually associated with injury or risk of injury to self or others, is frequently associated with symptoms in multiple psychological domains. Enhanced arousal and startle responses to previously innocuous stimuli are common, as are intrusive traumatic memories (flashbacks) of the triggering event, the numbing of emotional feelings, and impairments to social relationships. The identification of brain regions that show increased activation associated with the enhanced perception and memory for emotional events and associated feeling states enables the linkage of psychological mechanisms in conditions such as PTSD and phobias with their underlying neural substrates.

Abnormal cortisol regulation and adrenergic stress responses are also seen in PTSD, as is a reduction in hippocampal volume. Imaging studies showing a

similar reduction in hippocampal volume in endocrine disorders associated with chronically elevated cortisol levels, such as Cushing's disease, suggest an etiological role for stress hormones such as cortisol in this reduction in hippocampal volume. These conclusions are further supported by a recent study of healthy postmenopausal women, which showed a strong correlation between hippocampal volume and lifetime levels of perceived stress, suggesting an influence of stress on regional brain volumes even in the normal population.

Maladaptive cognitive interpretations of situations or events are central components of many emotional disorders such as depression and the anxiety disorders and are a feature focused on by many of the psychological therapies used in their treatment. Understanding the neural mechanisms mediating the modulation of emotional responses will be essential to developing a comprehensive neurobiological understanding of these disorders. Furthermore, a better understanding of these mechanisms offers the opportunity to develop more targeted approaches specifically focused on changing these maladaptive emotional reactions.

Communication between the Nervous System and the Immune System

Communication Channels between the Nervous System and the Immune System

Cytokine Interactions with the Nervous System

Clinical Implications of Neural-Immune Signaling

Glossary

<i>Cytokines</i>	Signal molecules released from immunocytes, supporting cells, or other cell types (endothelial cells) that can interact with other cells of the immune system and alter their intracellular capabilities.
<i>Immunocytes</i>	Cells of the immune system.
<i>Innervation</i>	The distribution of nerve fibers that end in association with a particular structure, region, or organ.
<i>Neurohormone</i>	A blood-borne signal of endocrine nature that is either derived from the brain directly or released from the pituitary gland due to neurally derived factors.
<i>Neuro-modulation</i>	The interaction of a neurally derived signal with a target cell that alters the intracellular capabilities of that cell through either genomic or nongenomic mechanisms.
<i>Neuropeptides</i>	Neural signal molecules derived from larger prohormones that consist of 3–100 or more amino acids; released from nerve endings, cells of neural origin, or cells of immune or endocrine origin.
<i>Neuro-transmitter</i>	A signal molecule released from nerve endings that can interact with specific receptors on target cells and alter either ion channels or second messengers following transduction.

Neuroimmunomodulation is the bidirectional signaling between the central nervous system (CNS) (the brain and spinal cord) and the cells and organs of the immune system. The CNS can send neuroendocrine signals that act on specific subsets of cells of the immune system and can also send direct neural

connections into lymphoid organs, where released neurotransmitters act on specific cell subsets of the immune system. These subsets of immunological cells possess a variety of receptors for neurohormones and neurotransmitters that permit signal transduction, influencing the activities and synthetic capacities of those cells. This direct neural-immune signaling modulates individual cellular functions as well as collective immune responses. Thus, the CNS can modulate immune responses, including innate immunity, cell-mediated immunity, autoimmunity, and complex collective immune reactivity to infections, cancer, and other challenges. This neural-immune circuitry permits behavioral influences, including those resulting from physical and psychological stressors, to modulate the activities of the immune system. The immune system, in turn, through the release of cytokines from specific subsets of cells, can signal neurons in the CNS and peripheral nervous system (PNS) directly and indirectly. This signaling influences the visceral and neuroendocrine functions of the hypothalamus, as well as the cognitive and affective functions of the forebrain. Some of the inflammatory cytokines, acting through the hypothalamus, can influence the activation of two highly significant components of the stress axes profoundly, the hypothalamic-pituitary-adrenal (HPA) axis and the sympathetic component of the autonomic nervous system (ANS). Therefore, the two great memory systems and communication systems of the body, the CNS and the immune system, are in constant communication with one another through biological signaling using endocrine hormones, neurotransmitters, and cytokines.

Communication between the Nervous System and the Immune System

Since the time of Galen, an association has been suspected between the mind or emotions and the clinical course or outcome of disease, as in Galen's description of melancholia and breast cancer. Early studies in humans pointed toward an association between psychosocial factors, particularly psychological stressors and the response of humans to various diseases thought to involve the immune system, such as bacterial and viral infections, allergic disorders, autoimmune diseases, and cancer. However, early correlational studies were unable to identify the communication channels through which such interactions between the nervous system and immune system could take place. Early studies in rodents

also demonstrated a link between psychological stressors and antibody responses, graft-versus-host responses, susceptibility to viral infections, and other reactions of the immune system, but, again, the neural communication channels were not elucidated in these early studies of the 1950s and 1960s.

Evidence for Neural-Immune Communication in Humans

Numerous studies of depressed individuals have reported diminished lymphocyte responses to proliferative stimuli (mitogens) or the diminution of other immune parameters such as natural killer (NK) cell activity or ratios of lymphocyte subsets. However, not all studies found such changes. Many variables influence the extent or presence of alterations in immunological parameters, including the type and severity of depression, time and treatment factors, and the age and gender of the patients. The most enduring findings reported that these diminished measures of immune response correlate best with the severity of depression and older age, particularly in men. The extent to which these diminished measures of immunological reactivity contribute to increased morbidity and mortality remains elusive.

Bereavement studies from the loss of a spouse also demonstrate diminished lymphocyte responses to mitogens and diminished NK cell activity, particularly in men. As in studies of other stressors in humans, the quality and extent of social support and the individuals' perception of control over their circumstances can act as buffers to ameliorate the stress-induced decline in measures of immunological reactivity.

The most extensive literature on neural-immune communications in humans is derived from studies of life stressors and psychosocial factors in selected groups of patients, particularly the studies of Janice Kiecolt-Glaser and Ronald Glaser. These investigators demonstrated diminished lymphocyte responses to mitogens, altered lymphocyte subsets, diminished NK cell activity, and increased antibody responses to viral epitopes on previously latent viruses in medical students during examination stress. Subsequent reports also demonstrated a diminished production of Th1 (cell-mediated) cytokines in medical students faced with examinations. Loneliness or lack of social support contributed to the presence and persistence of these alterations. Similar alterations in immune responsiveness (diminished mitogen responses and NK cell activity, and altered antibody or cytokine responses) have also been reported in a variety of other stressors, including marital separation and divorce, hostile behavior toward spouses in both recent and long-standing marriages, caregiving to a loved one with dementia (e.g., Alzheimer's disease),

and adaptation to a nursing home. In some of the marital studies, a significant impact of hostile behavior was noted on stress mediators, with the elevation of epinephrine and norepinephrine (NE), adrenocorticotrophic hormone (ACTH), growth hormone (GH), and prolactin. These important studies indicate direct links between behaviors or psychosocial factors, neuroendocrine and neurotransmitter mediators, and altered immune responses. It now appears that these links have direct implications for health through the modulation of wound repair, inflammation, NK cell response and tumor metastases, lymphocyte functions, and collective cell-mediated (vs. humoral) immune responses to infectious challenges by viruses and bacteria.

Positive emotions and positive factors also can modulate immune reactivity, often in a direction opposite to that of stressors. Social support interventions in nursing home subjects demonstrated an enhancement of some of the immunological parameters that were diminished previously. Lee Berk and colleagues have shown that mirthful laughter is accompanied by a diminution of stress mediators such as NE and cortisol and by enhanced NK cell activity and other immunological measures. Exercise that does not exceed 70–80% of capacity results in enhanced NK cell activity, enhanced lymphocyte mitogen responses, and enhanced measures of cell-mediated activity; exercise that exceeds these limits depresses many of these same parameters substantially. Due to the nature of the measurements of immune responsiveness in humans, limited mainly to blood samples, the extent to which these changes reflect the direct effect of mediators on individual cell functions, or the indirect effects of such parameters as altered cell trafficking, is not known. Some studies of various relaxation responses report the enhancement of some measures of immune response as well.

Studies in women with breast cancer by David Spiegel and colleagues and in patients with malignant melanoma by Fawzy Fawzy and colleagues have reported that structured psychological interventions involving counseling and peer support can extend longevity and enhance the quality of life. These provocative studies have evoked great interest in both scientific and lay communities and await further confirmation in multicenter trials and in studies in which neural-immune mediators and immunological measures are carried out in the same patients.

Caution is needed in studies of immune responses that accompany various stressors, positive behavioral and emotional factors, or structured interventions. Specific measures of immunological reactivity imply specific health consequences. For example, enhanced NK cell activity appears to aid in the innate response

to viral killing and in the killing of metastatic cancer cells, particularly when blood-borne. Enhanced cell-mediated immunity, production of Th1 cytokines such as interleukin (IL-2) and interferon (IFN- γ), boosts host responses to viral infections and appears to be protective in elderly individuals; human immunodeficiency virus (HIV)-positive individuals; and patients with a variety of cancers, including relatively nonimmunogenic cancers. However, enhanced cell-mediated T lymphocyte responses may be highly detrimental to an individual with an autoimmune disease such as multiple sclerosis; clinical trials with INF- γ showed an increased frequency of demyelinating attacks on the CNS. Thus, enhancing the immune system is a meaningless phrase unless we define (1) which parameters of immunological reactivity are enhanced, (2) which specific group of individuals is being studied, and (3) what specific immunological challenges the individuals are facing. The popular literature and lay understandings of this concept are virtually absent and need to be addressed.

Evidence for Neural-Immune Communication in Experimental Animals

A striking body of evidence for neural-immune communication in experimental animals comes from the conditioning studies of Robert Ader and Nicholas Cohen. Using a taste aversion model, they demonstrated that immune suppression from the administration of cyclophosphamide could be conditioned by a novel taste stimulus. This conditioned immune suppression was of sufficient functional magnitude that the conditioned rodents who were given the novel taste stimulus at a later time in their drinking water died of pneumonia; this agent had no effect in unconditioned animals. These investigators later studied conditioned immunosuppression in genetically autoimmune animals with a lupuslike syndrome that kills them early in life. These conditioned animals showed remarkably extended longevity without evidence of the lupus-related lymphadenopathy. As a further demonstration (one more pleasing to immunologists), Ader and Cohen demonstrated that an antigen itself (rather than a drug) could be paired with a novel taste stimulus to produce a conditioned enhancement of the magnitude of secondary antibody responses. Although the implications for application to humans facing difficult drug therapy with immune-reactive agents are highly promising, those studies are only now being pursued.

Studies in animals have investigated the immunological consequences of a wide range of physical and psychological stressors. In some circumstances, stressors such as extensive restraint result in suppressed NK cell activity, diminished lymphocyte proliferative

responses to mitogens, and even diminished cell-mediated and humoral immune responses. However, many complications arise in these stress and immunity studies. Sometimes, a stressor elicits enhanced immune responses rather than suppressed immune responses. Subtle differences in shock paradigms, related to frequency, intensity, and repetitions of the shocks, can produce the opposite effects, or no change at all, in immunological measurements. Even more perplexing is the finding that some stressors elicit the enhancement of one form of cell-mediated immune response and the suppression of a closely related but different cell-mediated immune response.

Thus, the impression expressed frequently in the lay literature that all stressors are bad for the immune system is simply incorrect. Some intriguing findings related to the exposure of rodents to stressors such as mild foot shocks involve the controllability of the stressors. Rodents who could not control the termination of the shocks showed a greater extent of immunological impairment than their counterparts who were able to control the termination of the shock and had less ability to respond to challenges from viruses, bacteria, or tumors. In general, acute laboratory stressors result in a wider and more complicated array of changes in immunological reactivity than chronic stressors. It is the chronic stressors that appear to be most likely to result in suppressed immune reactivity across a wide range of responses. Perhaps one of the most intriguing findings related to stressors and immune responses is their consequence for the progression of autoimmune diseases in experimental animals. Physical and psychological stressors, in general, protect against the progression of autoimmune symptoms and consequences; however, in the poststress interval, that benefit is lost or reversed, sometimes worsening the disease progression. A recent fascinating finding is the ability of IL-1 β to stimulate the corticotropin releasing hormone (CRH) system in the hypothalamus, thereby activating both the HPA axis (cortisol secretion) and the sympathetic nervous system (SNS; norepinephric, NE, neurotransmission). It appears that IL-1 β is one of the most potent activators of both of these stress axes compared with other physical and psychological stressors. Perhaps the immunological reactivity that results in the production of systemic inflammatory mediators should be considered at the top of the list of potent stressors in both experimental animals and humans.

One additional area of investigation that demonstrates a link between the nervous system and the immune system is the immunological consequences of direct lesions placed in the CNS. In general, lesion sites that result in altered immune responses are

found in the hypothalamus, the limbic forebrain (septum, hippocampal formation, amygdala, and some cortical regions), and brain-stem areas related to the regulation of autonomic outflow and processing or the reticular formation. These lesion studies suggest a complex array of circuitry that involves both excitatory and inhibitory neural connections that ultimately are able to alter the reactivity of specific portions of the immune system via neuroendocrine or autonomic outflow.

Communication Channels between the Nervous System and the Immune System

The CNS has two major routes of communication by which it can signal cells and tissues of the immune system. The first is the neuroendocrine channels that generally emanate from the hypothalamus and regulate the outflow of anterior and posterior pituitary hormones. Some of these hormones exert direct influences on immunocytes (cells of the immune system), whereas other anterior pituitary hormones act by stimulating additional hormones from target organs in the periphery. The second is the direct neural channels that provide anatomical nerve fiber connections between the CNS and lymphoid organs and tissues. These neural channels are either part of the ANS (and connect via a two classical two-neuron chain to the target structure) or part of the one-neuron sensory (afferent) connections from the periphery into the CNS. Some primary afferents are capable of releasing neurotransmitters both proximally, into the CNS, and distally, into the site of distribution of the sensory receptive elements. The autonomic nerve distribution to lymphoid organs and tissues derives principally from the sympathetic division of the ANS.

The immune system can signal neurons or supporting cells of the CNS and PNS principally via the release of cytokines. The cytokines can act on peripheral neuronal elements in the local paracrine environment and can act on CNS cells either through the actions of circulating cytokines or through the activation of primary afferents that activate central afferent autonomic circuitry.

Immunocytes Possess Receptors for Hormones and Neurotransmitters

Immunocytes, including lymphocytes (both B and T cells), macrophages/monocytes, granulocytes, thymocytes, stem cells, and other associated cell types, possess receptors for hormones and neurotransmitters. Some hormone receptors are present on the plasma membrane of immunocytes; their stimulation results in the altered activation of ion channels or the altered production of second messengers. Other

hormone receptors are found intracellularly and, when combined with a properly configured hormone (ligand), can exert genomic influences by acting as transcription factors or in combination with other transcription factors. The hormone–receptor complex can also alter intracellular transduction pathways. In addition, immunocytes possess neurotransmitter receptors on the plasma membrane. When activated by the appropriate ligand, these receptors on immunocytes can influence intracellular events through one or more second-messenger pathways. Some receptors for neurotransmitters (e.g., the β adrenoceptor) appear to be identical to their counterparts on neurons and peripheral target organs of the SNS, whereas other receptors (e.g., the substance P, SP, receptor) appear to be configured slightly differently from their neuronal counterparts. Immunocytes possessing this SP receptor respond more broadly to SP and substance K elements of the tachykinin family than does a neuron with its more narrowly responsive SP receptor.

Neurotransmitter and hormone receptors are not expressed by all immunocytes and, when expressed, are not distributed uniformly across all subsets or during all states of activation. For example, Virginia Sanders and others have demonstrated that β adrenoceptors, responsive to catecholamines such as NE and epinephrine, are expressed more abundantly on B lymphocytes than on T lymphocytes and more abundantly on T suppressor/cytotoxic (CD8) cells than on T helper/inducer (CD4) cells. Although β adrenoceptors are present on immature thymocytes, they increase in density during maturation. Activated T cells possess higher numbers of β adrenoceptors than resting T cells. Lymphocytes from aged animals possess higher numbers of β adrenoceptors than their younger counterparts. At first glance, this suggests an increasing sensitivity of these cells to catecholamines with age; however, these receptors on aged lymphocytes are poorly coupled with their G-protein and show a diminished transduction of cAMP via adenylate cyclase. Thus, many variables may influence the ability of neurotransmitters to influence immunocytes.

Immunocyte subsets possess receptors for a variety of neurotransmitters, including both α and β adrenoceptors, dopamine receptors, muscarinic cholinergic receptors, excitatory amino acid receptors, and peptidergic receptors (SP; calcitonin gene-related peptide, CGRP; somatostatin; vasoactive intestinal peptide, VIP; and opioid peptides, to name a few).

The signaling of immunocytes through neurotransmitter–receptor interactions may initiate direct intracellular changes that can be detected readily, or they may exert indirect effects that become apparent

mainly during signaling from a second ligand. For example, activation of the T-cell receptor with anti-CD3 antibody will result in the more robust production of the second messenger cAMP when β adrenoceptor activation is present than when it is absent. It is likely that neurotransmitters often act in synergistic (or countersynergistic) fashion with other neurotransmitters, hormones, cytokines, growth factors, and other signals; in this way, they resemble the dual-signaling and modulatory capacities of cytokines.

Neurohormonal Signaling of Immunocytes

A wide range of hormones, including those of the anterior pituitary, the posterior pituitary, and peripheral glands, can signal cells of the immune system and exert profound effects on the ability of the immune system to mount an appropriate defense response. The best-known hormonal system with regard to immune function, the HPA system (acting via CRH, ACTH, and cortisol), plays such an important and integral role in basic immunophysiology that Hugo Besedovsky proposed that the HPA axis is an integral component of the immune system itself. Although even a basic review of the hormonal effects on immune reactivity is far beyond the scope of this article, a few highlights are mentioned in selected areas.

The hypothalamic-pituitary-adrenal axis CRH, produced mainly in the paraventricular nucleus (PVN) of the hypothalamus, is released from axons into the private vascular channel of the hypophyseal-portal system. The resultant high concentration of CRH stimulates the release of ACTH from corticotrophs in the anterior pituitary. ACTH is released into the general circulation and activates cells in the adrenal cortex to release cortisol into the general circulation in humans (corticosterone in rodents). Both ACTH and cortisol exert effects on a variety of immunocytes. Interestingly, CRH is found in sites in addition to the PVN, such as macrophages, in a variety of peripheral organs. Thus, even CRH may exert hormonal influences on immunocytes directly, in addition to its contribution in activating ACTH and cortisol production.

CRH-producing neurons in the PVN are a major target of action for circulating inflammatory cytokines, especially IL-1 β , acting either directly or indirectly to enhance the activity of the CRH neurons. CRH neuronal activation resulting from either peripheral or central IL-1 β stimulation enhances the production of ACTH and cortisol via the HPA axis and, in addition, activates the hypothalamic-sympathetic axis, thus enhancing both of the major classical stress axes physiologically. Esther Sternberg

and colleagues showed that CRH hypothalamic neurons are important regulatory cells in autoimmune diseases. She studied genetically autoimmune-prone animals, such as the Lewis/N rat, to identify potential defects contributing to the susceptibility of these rats to autoimmune diseases. She found a lack of responsiveness of the hypothalamic CRH neurons following attempts to activate them by psychological stressors, neurotransmitter signaling, and the administration of cytokines. Sternberg concluded that the diminished capacity of these rats to activate the HPA axis following appropriate stimuli contributed to their inability to generate a cortisol-evoked suppression of unwanted cell proliferation during immune challenge, particularly by self-reactive clones of cells. When the hypothalamic CRH neurons in closely related autoimmune-resistant rat, the Fischer 344, were lesioned or blocked, these rats became as susceptible to autoimmune-provoking stimuli as Lewis/N rats. These important findings suggest that Besedovsky was correct in considering the HPA axis to be a vital physiological component of the immune system.

For many years, cortisol and other glucocorticoids were thought to be major immunosuppressive hormones. Dexamethasone and other such steroids were often given to patients for their anti-inflammatory or immune suppressing effects, including the treatment of autoimmune diseases. Studies of glucocorticoid effects on immunocytes have reported lymphocyte and thymocyte apoptosis; inhibition of T-cell proliferation; inhibition of cytokine production, such as IL-1 and IL-2; and suppression of a host of innate and acquired immune responses. Interestingly, work by Daynes and Araneo noted that physiological concentrations of glucocorticoids, in contrast to the massively suppressive effects of pharmacological doses of these agents, shifted the balance of cytokine production in T-helper lymphocytes from Th1 (diminished IL-2 and IFN- γ) to Th2 (enhanced IL-4 and IL-10), thus altering acquired immune responses away from cell-mediated immunity (Th1) and toward humoral immunity (Th2). Many researchers and clinicians have proposed that the maintenance of robust cell-mediated immunity is critical for protection against viral infections and some tumors and is necessary for maintaining a relative state of health in patients with HIV infection, some cancers (including some that are relatively nonimmunogenic), and immunosenescence in the elderly. ACTH has also been noted to exert a wide range of immune effects, including reduced IFN- γ production, increased NK cell activity, and complex effects on antibody production.

Dehydroepiandrosterone (DHEA) is an adrenal hormone that some investigators have reported as countering the effects of cortisol. DHEA can enhance

some cell-mediated immune responses, restore some immune responses in aged animals, and block some of the immune-suppressive effects of cortisol. The DHEA : cortisol ratio may be a good index of eustress activity (with positive effects on cell-mediated immune responses, such as moderate exercise), in contrast with distress from aversive stimuli and activities, such as maximal physical exertion in marathon running.

Growth hormone and prolactin GH is a hormone produced by cells of the anterior pituitary gland. A GH deficiency in many animals results in small, hypocellular primary and secondary lymphoid organs. The reconstitution of these deficient animals with GH restores cellularity to the lymphoid organs; restores T-cell development in the thymus; and restores antibody responses, cell-mediated responses, and NK cell activity. GH also potentiates cytotoxic T-lymphocyte activity. In animals with involution of the thymus, the administration of GH and prolactin restores thymic morphology and many T-lymphocyte functions. This reinforces the contention that GH exerts a particularly important influence on thymic function. GH also primes macrophages and neutrophils to produce superoxide anion, a functional component of phagocytosis. Surprisingly, GH is also produced by lymphocytes themselves and may act as a paracrine or autocrine signal for lymphocyte proliferation.

Prolactin is another hormone produced by cells of the anterior pituitary. The administration of prolactin contributes to the restoration of immune function in hypophysectomized animals and acts in a similar fashion with GH to help restore thymic cellularity and function in animals with involuted thymuses. Prolactin blockade decreases host resistance to some bacterial infections, such as *Listeria monocytogenes*. Mechanistic studies point toward a role for prolactin as a permissive factor or progression factor, necessary but not sufficient for IL-2-induced T-lymphocyte proliferation. A prolactin-like molecule has also been identified as a product of concanavalin A (Con A)-stimulated T lymphocytes and may be an important autocrine or paracrine lymphocyte growth factor, particularly in conjunction with a possible synergistic effect with estrogen.

Opioid peptides The opioid peptides are families of low-molecular-weight peptides, the endorphins, the enkephalins, and the dynorphins. They are found in the CNS, the pituitary gland, and peripheral structures such as the adrenal gland. In the brain, opioid peptide interactions with their receptors can induce

analgesia, exert profound behavioral changes, and alter outflow channels to the periphery that can modulate immune responses. Some of these changes can be blocked by naloxone and other opioid blockers, whereas others cannot. The opioid peptides are cleaved from larger prohormone peptides. For example, the precursor proopiomelanocortin (POMC) is cleaved to ACTH and β -lipotropin, the latter of which gives rise to β -endorphin. β -Endorphin levels increase in the serum in parallel with ACTH levels following some stressors, suggesting that β -endorphin may be an important stress-induced neuromediator with an influence on immunocytes or immune responses. Although a review of opioid peptide actions is beyond the scope of this article, we briefly mention of some immune effects of β -endorphin.

β -Endorphin reduces antibody production in mice through μ - and κ -opioid-receptor-mediated effects. β -Endorphin inhibits lymphocyte chemotactic factor in humans and may itself act as a chemotactic factor. Some additional β -endorphin effects are thought to be nonopioid-receptor-mediated, including enhanced Con A-induced T-lymphocyte proliferation in mice, reduced phytohemagglutinin (PHA)-induced T-lymphocyte proliferation in humans and the blockade of prostaglandin E1-induced suppression of lymphocyte proliferation in rats. The opioid peptides exert very complex and varied actions on immunocytes *in vivo* and *in vitro*; sometimes exert contradictory effects *in vitro* versus *in vivo*; and can act in synergistic fashion with other neural, endocrine, and immunological mediators.

Other hormones Many other hormones, in addition to those mentioned earlier, have been shown to influence immunocytes and immune function in a variety of *in vitro* and *in vivo* models. These hormones include thyroid-stimulating hormone (TSH), thyroid hormones, gonadal steroid hormones (estrogen and androgens), posterior pituitary hormones (oxytocin and vasopressin), and melatonin (produced by the pineal gland).

Nerve Fiber Connections with Lymphoid Organs: The Hard Wiring

Peripheral nerve fibers are found in primary lymphoid organs (the bone marrow and thymus), in secondary lymphoid organs (the spleen and lymph nodes), in mucosal-associated lymphoid tissue (the gastrointestinal tract and lung), and in the skin. Tracing studies have revealed the location of some (but not all) of these connections. The two major sources of connectivity are the ANS and the primary sensory system. In the ANS, the vast majority of connections derive

from the sympathetic division via a two-neuron chain, with the postganglionic component releasing NE as a major neurotransmitter. These SNS connections distribute adjacent to at least some components of all collections of lymphoid organs and tissues. Very few connections to lymphoid tissues derive from the parasympathetic division of the ANS. Classic two-neuron connections of the cholinergic parasympathetic system have not been identified in either the primary or secondary lymphoid organs; indeed, there is little evidence for cholinergic neurotransmission in these organs, despite the presence of muscarinic cholinergic receptors on some immunocytes found there. Parasympathetic connections that may influence immunocytes are found mainly in mucosal-associated lymphoid tissue and the skin.

A wide range of neuropeptides has been identified in nerve fibers in the lymphoid organs. Some of these neuropeptides (SP and CGRP) are thought to be associated mainly with sensory connections. However, very few tracing studies have demonstrated a primary sensory (afferent) origin for this neuropeptidergic innervation of lymphoid organs and tissues. Some peptides (neuropeptide Y, NPY) appear to be colocalized with other neurotransmitters in cells of the SNS. Some primary afferents, particularly the small SP fibers, have been shown to release their neurotransmitter from both proximal and distal arborizations of their axons. Thus, it is possible for a primary afferent cell to be activated and then release the neurotransmitter at the site in the periphery where the initial activating stimulus took place. It is clear that a much more thorough mapping of the cells of origin, distribution, and associations with target cells in the immune system needs to be accomplished for the nerve fiber connections that provide the innervation to cellular targets in the organs and tissues of the immune system.

Sympathetic noradrenergic nerve fibers Postganglionic sympathetic NE nerve fibers supply primary lymphoid organs, secondary lymphoid organs, and mucosal-associated lymphoid organs with innervation. These nerve fibers distribute along the vasculature, travel with smooth muscle structures such as the trabeculae, and arborize directly into the parenchyma where they form close junctional appositions (neuro-effector junctions) with cells of the immune system. The innervation that extends into the parenchyma is associated with specific compartments of lymphoid organs and maintains that compartmentation even when involution or loss of cellularity occurs. Some neuroimmunocyte appositions are as close as 6 nm (a gap junction is 2 nm, and a classical synapse in the

CNS is 20 nm). Felten and colleagues hypothesized that communication in the parenchyma of lymphoid organs occurs in both directions: (1) neurotransmitters released by sympathetic nerve endings can act on receptors on target cells of the immune system and (2) cytokines released by target cells of the immune system can modulate the extent of release of neurotransmitters such as NE. For the most part, sympathetic NE nerve terminals also colocalize NPY, although there are some terminals that contain only one and not the other. Extensive studies from the laboratory of David Felten and colleagues identified abundant innervation of lymphoid organs.

NE nerve fibers enter the bone marrow with the nutrient arteries, distribute along those arteries, and arborize extensively into the parenchyma, where they associate with stem cells and other constituents of the marrow. Most of these fibers appear to colocalize NPY. Many cells of the bone marrow possess adrenoceptors, especially β adrenoceptors. Studies using a three-dimensional bone marrow culture showed that catecholaminergic stimulation of bone marrow can augment granulocyte production. NE nerve fibers enter the thymus along the capsular surface and distribute through the septal system. Some NE fibers distribute into the thymic cortex and medulla and extend along the vasculature at the corticomedullary junction. Thymocytes possess adrenoceptors, with increasing numbers noted during thymocyte maturation. Some investigators have reported that catecholamines can suppress thymocyte proliferation through the activation of adenylate cyclase and generation of cAMP; however, this interaction may be more likely to occur during involution or during diminished cellularity, at which time the NE innervation is very dense.

NE nerve fibers enter the spleen with the splenic artery, travel along the trabecular system, and distribute extensively into the splenic white pulp. In the white pulp, NE nerve fibers follow the central artery of the white pulp, extend along the marginal sinus (where macrophages reside) and into the marginal zone, and distribute extensively into the periarteriolar lymphatic sheath. NE nerve terminals form close associations with T lymphocytes of both CD4 and CD8 subsets and with macrophages and NK cells. Very few NE fibers are found in the B-lymphocyte zones, the follicles. NE innervation appears to enhance cell-mediated immunity during the initiative phase of an immune response and has some inhibitory effect on humoral immunity in Th1-dominant animals.

NE nerve fibers enter lymph nodes with the vasculature in the hilar zone and with the capsular surface. These fibers distribute through the medullary cords,

where they associate with macrophages and other cells and arborize into the cortical and paracortical zone where T lymphocytes of both CD4 and CD8 subsets reside. As in the case of the spleen, very few NE terminals distribute into the B-lymphocyte zones, the nodules. In lymph nodes, NE fibers also enhance cell-mediated immunity and, in some cases, inhibit humoral immunity, particularly in the case of autoimmune-provoking stimuli. The denervation of these NE fibers in both the spleen and lymph nodes results in diminished cell-mediated immune responses, enhanced humoral responses in Th1-dominant animals, and increased severity of autoimmune-provoking stimuli. NE also appears to exert extensive influences on cell trafficking, particularly on NK cells and T lymphocytes. Even very low concentrations of catecholamines can result in the release of marginated and organ-localized NK cells into the circulation. Interestingly, during aging, the spleen and lymph nodes progressively lose their NE innervation, according to Denise Bellinger and colleagues, due to autodestruction by oxidative metabolites of catecholamines released into the paracrine environment by NE nerve terminals in these secondary lymphoid organs. When the NE innervation is restored in old animals, with the administration of growth factor-stimulating pharmacological agents (e.g., low-dose deprenyl), IL-2 and IFN- α production is enhanced markedly, NK cell activity is elevated, and T-cell proliferation is restored.

Noradrenergic innervation is also found in mucosal-associated lymphoid organs. In the gastrointestinal tract, these fibers distribute through T-lymphocyte zones and arborize in submucosal zones.

Neuropeptide-containing nerve fibers Extensive networks of neuropeptide-containing nerve fibers distribute into both the primary and secondary lymphoid organs. A few neuropeptides, such as NPY, are colocalized with NE sympathetic nerve terminals, but most neuropeptide-containing nerve fibers are independent of the known sympathetic innervation.

Neuropeptide Y-containing terminals appear to colocalize with NE as a component of the sympathetic innervation in the bone marrow, thymus, spleen, and lymph nodes, although some non-NE NPY+ nerve terminals are present in the lymphoid organs. NPY is also found in the platelets in the spleen and is found in the circulation, apparently from release following sympathetic activation. Some immunocytes possess receptors for NPY.

SP and CGRP are found frequently as colocalized neuropeptides in non-NE nerve terminals in all lymphoid organs and tissues, as well as the skin. SP nerve fibers have been identified along the

vasculature and in the parenchyma in the bone marrow, thymus, spleen, and lymph nodes. CGRP is often colocalized with SP; however, in some sites, CGRP-containing nerve fibers distribute independently (e.g., adjacent to antigen-presenting Langerhans cells in the skin).

SP receptors have been identified on both T and B lymphocytes as well as on granulocytes and mast cells. SP is a potent regulator of inflammation and can induce extravasation and edema, attract other pro-inflammatory cells and mediators, and exacerbate inflammation in sites such as joint spaces in rheumatoid arthritis. SP can also enhance polyclonal immunoglobulin (Ig)A and IgM production by gut-associated lymphoid tissue, enhance T-cell proliferation and IL-2 production in the secondary lymphoid organs, and increase some antibody responses and lymphocyte-proliferative responses. Many of these immunoenhancing effects of SP can be counteracted by somatostatin, but an extensive understanding of somatostatin innervation of lymphoid organs is not yet available. In the skin, CGRP acts as a potent inhibitory factor on antigen presentation by Langerhans cells.

VIP-containing nerve fibers are present in Peyer's patches in the gut, thymus, and spleen. VIP receptors are present on some T lymphocytes; Cliff Ottaway showed that their expression can enhance the migration of these T cells into the gut-associated lymphoid tissue and the mesenteric lymph nodes, whereas their absence prevents such migration. VIP can also inhibit T-lymphocyte proliferation.

Many other neuropeptides have been found in the primary and secondary lymphoid organs. These neuropeptides include the opioid peptides, cholecystokinin, neurotensin, CRH, somatostatin, and galanin. Little is known about the details of the functioning of these neuropeptide-containing nerve fibers. It is particularly difficult to discern the unique role of specifically compartmentalized neuropeptides, such as the opioid peptides, that appear in neurons, pituitary cells, and immunocytes.

The origin of cell bodies for most of the neuropeptide-containing nerve fibers that distribute into the lymphoid organs and tissues is not known. Thus, we do not even know if they are components of the primary afferent system, the sympathetic or parasympathetic divisions of the ANS, or the enteric nervous system. Neuropeptide receptors are present on many specific subsets of lymphocytes, macrophages/monocytes, and other lymphoid cells. We do not yet know the details of the distribution of these receptors, the details of the second-messenger pathways in specific subsets of immunocytes, or the functional role of these receptors in immunoregulation.

Immunocyte Production of Neuropeptides

Ed Blalock, Eric Smith, and colleagues made the remarkable discovery that cells of the immune system, particularly lymphocytes and macrophages/monocytes, can synthesize neuropeptides directly. They showed that some immunocytes can synthesize the POMC gene following stimulation by a virus (Newcastle's disease) or a releasing factor (CRH). The resultant neuropeptides produced and released by the immunocytes are, for the most part, identical to their counterparts made by neurons and pituicytes. Immunocytes have been reported to produce the POMC-derived products ACTH and β -endorphin, TSH, and CRH. In some instances, the same neuropeptide can be produced by neurons, pituicytes, and immunocytes in the periphery.

Cytokine Interactions with the Nervous System

Immunologically derived mediators, the cytokines, can act directly or indirectly to influence the activity of neurons in the CNS and PNS. In addition, some supporting cells of the nervous system (microglia and astrocytes), and even a small subset of neurons in the CNS and PNS, can produce cytokines directly, particularly IL-1 β . The most extensively studied cytokines with regard to effects on CNS neurons and CNS behavior are the pro-inflammatory cytokines, IL-1, IL-6, and tumor necrosis factor (TNF)- α . IL-1 β can act on neurons in the CNS, particularly on hypothalamic neurons, and can induce fever, slow-wave sleep, lethargy, loss of appetite, diminished reproductive behavior, and other classic illness behaviors. Interestingly, this illness behavior can be induced by IL-1 β injected by intracerebroventricular (ICV), intraperitoneal (IP), or intravenous (IV) routes; the ICV route requires lower concentrations of IL-1 β to induce the illness behavior than the IP or IV routes.

Many mechanisms have been proposed by which IL-1 β may exert its actions on the CNS:

1. IL-1 β may cross the blood-brain barrier directly, enter into the cerebrospinal fluid, and then act directly on neurons. Banks and colleagues reported such a transport system, although the greatest extent of crossing of IL-1 into the CNS occurs in the cortex, not the hypothalamus.
2. IL-1 β may act on the cells of the organum vasculosum of the lamina terminalis to release mediators such as prostaglandin E₂, which, in turn, activates preoptic neurons.
3. In the circulation, IL-1 β may act on endothelial cells in the brain vasculature, resulting in the

release of mediators such as nitric oxide and prostaglandins that, in turn, activate neurons.

4. IL-1 β may act on vagal afferents (via paraneurons) or on other afferents, according to the work of Watkins and Maier, stimulating cells in the nucleus solitarius complex, which, in turn, activate the hypothalamus.

It is likely that a combination of all of these routes operates to some extent in physiological circumstances.

IL-1 β also can activate the HPA axis through its actions on the CRH neuronal system of the PVN. To a lesser extent, so can IL-6 and other cytokines. This activation of the CRH system requires the input of the A1 and A2 brain-stem NE projections to the PVN, suggesting an action of IL-1 β on the central NE nerve terminals. IL-1 β also activates the hypothalamic-spinal cord system, which enhances sympathetic outflow from the intermediolateral cell system of the thoracolumbar spinal cord. Thus, cytokines that activate the HPA axis and the SNS can, in and of themselves, be considered as classical stressors. In addition, viral infections and immune responses that result in the production of pro-inflammatory cytokines, such as IL-1 β , also should be considered as classic stressors.

Inflammatory mediators also appear to be involved in some neurodegenerative diseases, such as Alzheimer's disease. IL-1 β and many other inflammatory mediators, complement components, and acute-phase proteins can be found at the site of plaque formation and neuronal degeneration in the brains of patients with Alzheimer's disease. The long-term administration of nonsteroidal anti-inflammatory medication or specific COX-2 inhibitors appears to diminish the inflammatory response and may protect against the progression of this disease.

In the PNS, both IL-1 and IL-2 appear to act on nerve terminals of the sympathetic NE system in secondary lymphoid organs and modulate the release of NE. These findings of cytokine modulation of central and peripheral neuronal activities indicate that the immune system and nervous system are in constant communication with one another on a continuing physiological basis.

Clinical Implications of Neural-Immune Signaling

At the most basic level, neurohormones and neurotransmitters can regulate the individual cellular functions of immunocytes, such as the proliferation, differentiation, maturation, expression of cell adhesion molecules (influencing trafficking); expression of specific cell markers; synthesis of specific cell

products (cytokines, immunoglobulins, and growth factors); or expression of specific portions of the genome. This can occur wherever the cell encounters an appropriate ligand, whether in an organ or in the blood.

At a more integrative level, neurohormones and neurotransmitters can also modulate immune responses, the collective interactions of multiple cell types that result in a reaction to challenge. These neural signals may either modulate aspects of innate immunity (e.g., location, number, and activity of NK cells) or modulate the acquired immune responses of both cell-mediated and humoral types. The final outcome depends on the collective impact of the specific signal molecules on antigen-presenting cells, accessory cells, lymphocytes, and any other cell types that contribute to the overall response.

The final clinical outcome is neural modulation of (1) the host response to viral, bacterial, or parasite infections, including both progression and latency; (2) wound healing; (3) inflammatory responses; (4) autoimmune reactivity; (5) immune senescence in old animals; and (6) the progression, metastatic spread, and recurrence of some specific cancers. In some instances, a single neurally derived signal may exert a predominant influence. In other instances, the collective interaction of glucocorticoids, other neurohormones, catecholamines, and neuropeptides all may contribute to the end effect. Studies demonstrate that many of these neural signals synergize with cytokines, growth factors, hormones, and other neural signals. This suggests that elucidating the integrated physiological influence of neural signaling on immune reactivity, and its potential to alter the outcome of disease processes, is a daunting but rewarding challenge.

Inflammation and Neuroinflammation: General Considerations

Neuroinflammation in Stroke

Neuroinflammation in Multiple Sclerosis

Neuroinflammation in Alzheimer's Disease

Summary

Glossary

<i>Alzheimer's disease</i>	A neurological disorder of progressive loss of cognitive functions occurring mostly in the elderly due to the accumulation of protein deposits that damage neurons and activate glial cells.
<i>Alzheimer's plaque</i>	Insoluble deposits of aggregated β -amyloid protein that accumulates in the brain and cerebral blood vessels of patients with Alzheimer's disease. Amyloid plaque triggers inflammatory responses that contribute to the death of neurons and progressive dementia.
<i>Cytokines</i>	A family of secreted proteins originally identified as products of leukocytes that serve in innate and specific immune and inflammatory reactions. Cytokine regulate diverse functions including cell growth, differentiation, function, and disease and are regarded as pleiotropic mediators.
<i>Inflammation</i>	A localized protective response that follows tissue injury and aims to destroy hostile agents, resolve tissue damage, and aid in repair and rehabilitation. Inflammation involves local vascular responses, leukocyte recruitment, and tissue cell activation stimulated by both local and systemic humoral factors.
<i>Interleukins</i>	A family of cytokines produced by leukocytes in natural immune reactions that serve to activate or modulate the function of other leukocytes as well as non-hematopoietic cells.
<i>Leukocytes</i>	White blood cells that are produced in the bone marrow and lymphatic tissue and circulate in the blood. White blood cells are responsible for immune

surveillance, innate immunity, and inflammation as part of host defense and tissue repair. In certain conditions, certain leukocyte subsets can mediate toxic reactions that lead to autoimmune diseases and chronic inflammatory diseases. A subset of white blood cells that are responsible for innate and specific immune reactions. T-lymphocytes are the central arm of the acquired cellular immunity and carry receptors that largely recognize antigens of foreign origin. Following clonal expansion, T-cells acquire the ability to clear the foreign invaders. B lymphocytes are the central arm of the humoral immune response. They largely recognize soluble antigens via immunoglobulin on their surface, upon which they differentiate to memory B cells.

A noninvasive imaging method that deploys brief magnetic pulses that polarize hydrogen atoms and then monitors energy emission. High-resolution images of soft tissue, particularly brain and spinal cord, are generated by computer algorithms. Tissue structure imaged via computerized algorithms can be deduced by differences in emission densities.

A neurological disease characterized by discrete white matter lesions (demyelination) and typified by intermittent, progressive, yet variable loss of motor and sensory (speech and visual) function and sometimes death.

Paired helical filaments of tau protein that accumulate inside neurons. Neurofibrillary tangles are one of the pathological hallmarks used to confirm the diagnosis of Alzheimer's disease at autopsy.

Short and limited stress conditions that modulates tissue vulnerability to subsequent injurious events.

Lipid mediators that are produced from fatty acids and serve in local and systemic functions of diverse tissues and organs. Certain prostaglandins participate in immune and inflammatory reaction, including leukotriene B₄ and thromboxane A₂.

Abrupt ischemic or hemorrhagic event in the brain that leads to loss of motor, sensory, and cognitive functions or death.

Inflammation and Neuroinflammation: General Considerations

Inflammation is a fundamental, carefully orchestrated, and highly conserved reaction of the organism meant to protect, defend, and amend diverse forms of injury. Inflammation (as well as innate immune responses) is critical for the organism's survival, yet in specific occasions, these reactions could result in a detrimental outcome. While inflammation features prominently in injuries to peripheral tissue, the situation is quite different in the central nervous system (CNS). The brain has long been considered an immunologically privileged organ. This notion is based on observations that tissue transplants into the CNS are not well rejected by the immune system, and inflammatory cells and mediators are sparse compared to peripheral tissues. The anti-inflammatory and anti-apoptosis environment in the brain and the limited access of brain-derived antigens to lymphoid organs may contribute to its immune seclusion. However, recent studies in infectious and autoimmune models have challenged this view. Injuries to the CNS activate cells within the CNS, called microglia, that like the peripheral monocyte system are capable of releasing a plethora of inflammatory mediators as well as activation of immune permissive molecules such as MHC class I. Proteins that are released from brain cells during injury can provoke acute and chronic inflammatory reactions in which both brain cells and circulating immune inflammatory cells participate.

Neuroinflammation in Stroke

Stroke Prevalence and Epidemiology

Stroke is a major medical emergency due to the resulting high rate of mortality and morbidity. In the United States alone, about 750,000 strokes, resulting in about 150,000 deaths, are estimated annually, which makes stroke the third leading cause of death in the United States. In addition, stroke management incurs a high burden of health costs due to prolonged rehabilitation, permanent (~30%) residual deficits, and loss of productive professional capabilities. The incidence of stroke has been on the decline from 1980 to 1990, primarily due to advances in aggressive management of key risk factors such as hypertension, atherosclerosis, and lipid disorders; lifestyle modifications (smoking); and in recent years, improved time to admittance to health facilities that are better equipped and organized to diagnose and treat strokes in specialized stroke care units. However, the incidence of stroke has not decreased in recent years in most of the industrialized countries while the prevalence has

actually increased due to the aging population and increased rates of comorbidities such as diabetes, heart failure, and the metabolic syndrome. In spite of the medical severity of stroke, its prevalence, and health burden, little progress has been realized in the treatment of this condition. The only specific, pharmacological treatment registered for stroke is tissue plasminogen activator (tPA), which enhances thrombolysis. This agent, however, finds limited utility (2–5% of admitted patients) due to substantial limitation of time to administration (3 h) and associated toxicity. In addition, no mortality benefits have been proven in prospective clinical trials with thrombolysis agents.

The reasons for the difficulties in discovering and developing new drugs for treatment of stroke are complex. Likely causes for failure to discover new drugs include poor understanding of the mechanism of neuronal death in stroke, which results in development of inadequate therapeutics. Also, the lack of proper experimental models for this human condition and limited insightful translational medicine may contribute. Recently, recognition of the role of inflammation in stroke has emerged, which may provide new opportunities to discover and develop effective treatment for stroke.

Cells and Mediators in Neuroinflammation in Stroke

Cerebral ischemia is marked by rapid activation of microglia, the brain cells that are part of the innate immune and inflammation cellular elements along with infiltration of inflammatory cells from the circulation into the ischemic territory (see [Figure 1](#)). Experimental stroke models revealed that early accumulation of blood-borne inflammatory cells in the ischemic brain persists for days to weeks after the initial insult. The early infiltration of polymorphonuclear cells (also called neutrophils) into the capillaries of the ischemic zone parallels the early activation of the glia cells (microglia and astroglia). Monocytes arrive in the injury zone much later, around 12–24 h after the ischemic injury, and are rapidly transformed into tissue macrophages displaying aggressive phagocytosis. Other immune/inflammatory cells such as lymphocytes are also observed at later time points. The significance of the exogenous leukocyte infiltration into the ischemic brain is controversial. The presence of leukocytes in the capillaries was argued to contribute to low or no flow in the capillaries due to clogging that exacerbates the ischemic insult. Furthermore, the gamut of toxic mediators released by the activated leukocytes, e.g., reactive oxygen radicals, proteases, and cytokines, has also been suspected to cause

inhibiting the polymorphonuclear leukocyte adhesion to the endothelium) have failed to show efficacy.

Chemokines

Chemokines are a family of more than 50 structurally and functionally related proteins involved in inflammatory cell recruitment. These relatively small proteins are usually subdivided into four subfamilies on the basis of their structural conservation of cysteine residues. Chemokines and their receptors are constitutively expressed in normal brain cells such as microglia, astrocytes, and neurons throughout the CNS, albeit at very low levels. As shown in [Figure 1](#), rapid expression of many chemokines takes place in response to acute ischemic brain injury, which corresponds with cytokine and leukocyte adhesion molecule expression. Most prominent activation has been documented for MCP-1 (monocyte attractant protein-1), interleukin-8, interferon-inducible protein-1, macrophage inflammatory protein-1, and fractalkine. While these chemokines and others seem to be expressed in the location and at the time that could lend them a role in propagation, aggravation, or repair of the ischemic injury, no agent to date has been deployed in clinical trials in stroke or other brain injury conditions. Experiments with prototypic inhibitors of certain chemokines have shown the potential for better recovery following stroke, yet proof of the concept has not been obtained in clinical studies.

Proteases and Matrix Proteins

Matrix metalloproteinases (MMPs) and serine proteases including tissue and urokinase plasminogen activators (tPA and uPA) are two large and important neutral protease gene families that are involved in the neuroinflammatory response to brain ischemia. These proteases have been the subjects of extensive research in other human diseases such as cancer and arthritis, and diverse inhibitors for many of these proteases have already been deployed to assess their role in stroke. The major pathophysiological role of MMPs has been disruption of the blood–brain barrier (BBB) and hemorrhagic transformation following ischemia. These proteases are induced, processed, and released from diverse cellular elements such as activated microglia within the ischemic zone and invading neutrophils and macrophages. However, MMPs and other proteases have many more functions that can bear on both tissue injury and repair. Angiogenesis, matrix remodeling that enables cells migration, axonal navigation, and cell–cell communication are important, understudied functions. While many MMP inhibitors have been synthesized, and some shown efficacy in

mitigation of stroke outcome in experimental models, none has been tried in human stroke. Issues regarding specificity, potency, and brain access (crossing the BBB) pose significant limitation for human trials.

Other Inflammatory Mediators

Ischemic conditions to the brain result in activation of numerous biochemical pathways including lipid degradation, neurotransmitter release, and oxygen radical generation. Most of these mediators are released in large quantities in ischemia, yet mostly in a short period of time. Lipid products such as prostaglandins (PGs), thromboxane A₂ (TXA₂), and leukotrienes B₄ (LTB₄) are potent inflammatory agents that induce strong chemotactic stimuli that facilitate inflammatory cell migration into the brain. Phospholipid products such as platelet-activating factor (PAF), a potent proinflammatory mediator, may also be important. However, while potent antagonists to PGs, TXA₂, and LTB₄ have been discovered, none has been tried as a potential therapeutic in stroke. Reactive oxygen radicals (RORs) have been extensively reported as a major response to brain ischemia. RORs via activation of nuclear factor- κ B (NF κ B) elicit diverse transcriptional events that lead to synthesis and release of many cytokines, interleukins, and other inflammatory mediators. Experimental studies with numerous antioxidant compounds have been most promising, although none has demonstrated efficacy as yet in human clinical trials.

Neuroinflammation in Multiple Sclerosis

Multiple Sclerosis: Epidemiology and Pathology

Multiple sclerosis (MS) is the most common neurological disease affecting young adults in the Western world, affecting 0.05–0.15% of Caucasians. MS prevalence varies depending on the genetic background. It is much more prevalent in Caucasians than in Africans and Asians. The disease usually begins in young adulthood, and it affects women more frequently than men. In 80–90% of cases, MS starts as a relapsing–remitting course, but over time, the number of relapses decreases, with most patients experiencing progressive neurological deficits that occur independently of relapses. In 10–20% of patients, MS begins as a primary progressive course without acute relapses. In the relapsing–remitting form of MS, acute lesions in the white matter of the brain, identified by magnetic resonance imaging (MRI), can resolve spontaneously. Disruption of the BBB, demyelination, and edema are indicative of an inflammatory process. In progressive stages, global brain atrophy and disability evolve. Contemporary concepts define MS as a chronic immune and inflammatory

disease of the CNS that is focused in the myelin areas of the CNS and spinal cord resulting in axonal demyelination. The originating causes of MS are unknown, but it is widely believed to be an autoimmune and inflammatory disease process.

Inflammatory Cells and Mediators in Multiple Sclerosis

The hallmark of the brain lesion in MS is a plaque of demyelination in the white matter area of the brain where B cells, T cells, macrophages, and activated microglia are notable. The inflammatory changes are accompanied by neuronal and oligodendrocyte (myelin-producing cells) loss and astrocyte (a type of glia cell) activation. These fundamental observations were fortified by observations in an experimental model of MS, experimental allergic encephalitis (EAE), in which myelin proteins were identified as the cause of EAE. Furthermore, adoptive transfer studies suggested that CD4⁺ T cells could transmit the disease to naive animals. Further research identified cytokines released from T helper 1 (Th1) such as interferon- γ (IFN γ), TNF β , and IL-2 as well as the proinflammatory cytokine TNF α as the primary disease mediators. By contrast, T cells that secrete IL-4, IL-5, IL-10, and IL-13 were viewed as immune protective mechanisms. Thus, the Th1 cells have taken center stage in MS research based on information obtained in the EAE model that also shares many similarities to human MS.

However, this simplistic hypothesis has been challenged by studies that cast doubts on the distinction between Th1 and Th2 cytokines as mediators of MS and that also suggested a role for Th2-secreted cytokines as well as another subset of T cells, Th0, which secrete cytokines of both Th1 and Th2 cells. Furthermore, B cells are also likely to play a role in the mechanism of brain lesions in MS as well as the brain innate immunity and especially the microglia, which upon activation provide a proinflammatory milieu, which is permissive for T cell activation.

Immune and Inflammatory Modulators in Treatment of MS

There are currently three different immunomodulatory therapies that have been approved for the treatment of relapsing-remitting MS, as they have been shown to improve clinical or MRI symptoms and signs. These are recombinant IFN- β -1b (Betaseron and Betaferon); recombinant IFN1a (Avonex and Rebif), and glatiramer acetate (copolymer-1 or Copaxone). The discrete mechanism of action of any of these drugs is not entirely clear, but slowing disease progression toward sustained disability or annual exacerbation rate of the disease and reduction in MRI lesion burden has been demonstrated.

Neuroinflammation in Alzheimer's Disease

Alzheimer's Disease: Epidemiology and Pathology

Alzheimer's disease (AD) is the most common cause of dementia in the elderly population and the fourth leading cause of death in persons over 65 years old. AD is an incurable and progressive disease that affects millions of people worldwide. A prevalence of 10% has been cited in developed countries, with doubling in frequency every 5 years from the age of 65 to 50% at the age of 90. AD carries a substantial economic burden due to the need for intensive patient care. AD was originally described in 1906 by Dr. Alzheimer, a pathologist who noted prominent pathological features in brain of deceased patients that suffered from severe dementia. There are three pathological hallmarks in AD brain: (1) senile plaques, now known to be composed from deposits of β -amyloid protein, (2) neurofibrillary tangles, and (3) inflammation. AD etiology is heterogeneous, with about 10% of cases associated with a strong familial background and Mendelian inheritance pattern. Certain mutations in chromosome 1, 14, and 21 were identified in addition to or association with polymorphism of the ApoE gene. Metabolic and nutritional factors are often cited as confounding if not causal factors.

Neuroinflammation in Alzheimer Disease

The inflammatory condition in AD is quite different from that in stroke or MS. Most prominently, it lacks the classical T and B cell immune component so notable in MS and lacks the systemic inflammatory cell infiltration of neutrophils and macrophages seen in stroke. It is believed that the inflammation in AD is a result of microglia and astrocyte activation by the plaque material of aggregates of β -amyloid protein. In addition, advanced glycation end products (AGE) and their receptor, RAGE, have recently been implicated in the neurotoxicity of AD. Cytokines and interleukins including TNF α , IL-6, IL-1, and macrophage colony-stimulating factor (M-CSF) are the most likely mediators generated by the activated microglia and astrocytes. In addition, RORs and complement factors are often cited as players in the inflammation cascade of AD. Although the significance and contribution of inflammation to the progression of AD are a topic of debate, recent clinical (the Rotterdam Study) and epidemiological research on the use of anti-inflammatory medications in AD suggests a significant correlation between inflammation and neurodegeneration. An important set of inflammatory mediators of a potential source of therapeutics are the cyclooxygenase (COX) products of arachidonic

acid metabolism, especially those generated by the COX-2 enzyme complex.

Anti-inflammatory Therapy in Alzheimer's Disease

Current treatment of AD patients is based on drugs that are supposed to increase brain levels of acetylcholine (a neurotransmitter that is associated with cognitive function). This treatment has modest and partial efficacy. Nonsteroidal anti-inflammatory drugs (NSAIDs) are presumed to have beneficial effects in AD due to reduction in microglia COX-1 or COX-2 action. However, the fact that patients who are treated with NSAIDs for reasons other than AD, such as rheumatoid arthritis, are not particularly protected from AD cast doubt on the potential efficacy of these agents. Reports on the possible efficacy of aspirin in reducing AD-associated dementia may support the COX-1/2 hypothesis since aspirin inhibits COX-1 action. Reducing platelet reactivity might be a key part of aspirin benefits. The potential of other inflammatory mediators to serve as therapeutic targets for AD remains a subject of intensive research.

Summary

Immune and inflammatory cells and mediators play an important role in health and disease. The brain is unique in its ability to secure an immune privileged environment, yet brain cells can launch inflammation when activated by an aberrant biochemical milieu (amyloid accumulation) or a physiological condition (ischemia). Brain injuries also result in the exposure to systemic immune and inflammatory processes that could contribute to damage but also provide critical repair elements. Only multiple sclerosis has gained new therapeutic opportunities in the form of immune modulators, albeit at limited efficacy. It is hoped that better understanding of the role immune and inflammatory cells play in brain diseases and injuries could lead to novel and effective treatment.

Glossary

<i>Anxiety</i>	A state of apprehension, uncertainty, or fear resulting from the anticipation of a realistic or fantasized threatening event or situation.
<i>Depression</i>	A mood disorder characterized by symptomatic criteria such as chronically depressed mood; low self-esteem; feelings of hopelessness, worthlessness, and guilt; and recurrent thoughts of death and suicide.
<i>Neuropeptide Y (NPY)</i>	A 36-amino-acid neuropeptide that is one of the most abundant within the central nervous system of all mammals, including humans.
<i>Neuropeptide Y receptors</i>	Receptor molecules for neuropeptide Y and the related peptides polypeptide YY (PYY) and pancreatic polypeptides (PP); they include the Y ₁ , Y ₂ , Y ₄ , Y ₅ , and Y ₆ subtypes, all of which couple to G-proteins and inhibit the production of cAMP.
<i>Sedation</i>	A reduction of anxiety, stress, irritability, or excitement, often by using a drug.

Neuropeptide Y (NPY) was isolated from porcine brain more than 2 decades ago and is a member of a large family of peptides that also include polypeptide YY (PYY) and the pancreatic polypeptides (PP). NPY is a 36-amino-acid peptide and is one of the most

abundant peptide expressed in the central nervous system (CNS) of all mammals, including humans. It is also one of the most conserved peptides in evolution, suggesting that it has an important role in the regulation of basic physiological functions. At present, five NPY receptor subtypes have been cloned and designated: Y₁, Y₂, Y₄, Y₅ and Y₆. All of them couple to G-proteins and inhibit the production of cAMP. In the rat brain, the Y₁ receptor has predominant expression in the cerebral cortex, thalamus, and brain-stem nuclei. The Y₂ receptor is abundantly expressed in the hippocampal formation and brain-stem nuclei. This subtype is considered to mostly act as presynaptic autoreceptors that provide negative feedback to NPY-ergic nerve terminals to modulate NPY release. There are only low levels of expression of the Y₄ receptor in the brain; *in situ* hybridization signals of the Y₅ receptor mRNA and its translated protein are seen in the olfactory bulb, hippocampus, and hypothalamic regions. The Y₆ receptor is not expressed in the rat and is nonfunctional in humans and primates. NPY has important modulatory functions in the immune and cardiovascular systems, circadian rhythms, food intake, and seizure activity. NPY is consistently involved in stress and anxiety-related behaviors and there is increasing support for the role of NPY in mood disorders such as depression and in various forms of addiction.

The Effect of Stress on Central Neuropeptide Y Signaling

NPY is considered an important neuromodulator in the regulation of anxiety-related behaviors. Several studies have shown that exposure to acute and chronic stress paradigms such as physical immobilization produces widespread changes in NPY expression throughout the CNS. For example, 1 h of restraint stress in Sprague–Dawley rats decreased NPY mRNA levels and NPY-like immunoreactivity (NPY-IR) by 30% in the amygdala; 2 h following restraint stress, NPY mRNA decreased by 35% in the neocortex and amygdala. However, 10 h after restraint stress, NPY-IR increased 23% in the hypothalamus. Another study

Table 1 Summary of the effects of exogenous NPY on anxiety-related behaviors^a

<i>Model</i>	<i>Treatment</i>	<i>Effect</i>	<i>Source^b</i>
Open field	ICV NPY	Dose-dependent anxiolytic effect	14
	NPY Y ₁ agonist: ICV [D-His ²⁶]NPY	Dose-dependent anxiolytic effect	14
	NPY Y ₂ agonist: ICV C2-NPY	No effect	14
	NPY Y ₅ agonist: ICV [cPP(1–7), NPY(19–23), Ala ³¹ , Aib ³² , Gln ³⁴]hPP	Anxiolytic-like effect	14
Elevated plus-maze	ICV NPY	↑ Time on open arms	7
		Dose-dependent anxiolytic effect	14
	ICV PYY	↑ Time on open arms	3
	ICV NPY(2–36)	↑ time on open arms	3
	NPY Y ₁ agonist: ICV [D-His ²⁶]NPY	Dose dependent anxiolytic effect	14
	NPY Y ₁ antagonist: ICV BIBP3226	Anxiogenic-like effect	9
	NPY Y ₁ antisense: ICV; CeA NPY Y ₁ antisense	Attenuated NPY-induced anxiolytic effect	4, 15
	NPY Y ₂ agonist: ICV C2-NPY	No effect	14
	NPY Y ₅ agonist: ICV [cPP(1–7), NPY(19–23), Ala ³¹ , Aib ³² , Gln ³⁴]hPP	Anxiolytic-like effect	14
	NPY Y ₁ /Y ₄ /Y ₅ agonist: ICV [Leu ³¹ , Pro ³⁴]NPY	↑ Time on open arms	3
	NPY Y ₂ /Y ₅ agonist: ICV	↓ Time on open arms	7
	NPY(3–36)	No effect	9
	ICV NPY	↑ Transitions (anxiolytic-like effect)	11
	BLA NPY	↑ Social behavior	13
	Septum NPY	↑ Social behavior	8
Light–dark box Social interaction	NPY Y ₁ antagonist: BLA BIBO3304	Blocks NPY-induced ↑ in social behavior	13
	NPY Y ₂ agonist: BLA C2-NPY	↓ Social behavior	12
	NPY Y ₅ agonist: BLA [cPP(1–7), NPY(19–23), Ala ³¹ , Aib ³² , Gln ³⁴]hPP	Anxiolytic-like effect	12
	NPY Y ₂ /Y ₅ agonist: BLA NPY(3–36)	Anxiolytic-like effect	12
	NPY Y ₅ antagonist: BLA Novartis 1	Blocked the anxiolytic-like effect of NPY(3–36)	12
	IP CGP71683A	No effect	10

Vogel conflict	ICV NPY	Anticonflict/anxiolytic-like effect	7
Geller–Seifter	ICV NPY	Anticonflict/anxiolytic-like effects	1, 2, 6
	NPY Y ₁ /Y ₄ /Y ₅ agonist: ICV [Leu ³¹ , Pro ³⁴]NPY	Anticonflict/anxiolytic-like effects	5
Fear-potentiated startle	ICV NPY, PYY, NPY(2–36)	↓ Startle response	3
	NPY Y ₁ /Y ₄ /Y ₅ agonist: ICV [Leu ³¹ , Pro ³⁴]NPY	↓ Startle response	3
	NPY Y ₂ antagonist: ICV NPY(13–36)	No effect	3

looked at repeated stress in Wistar–Kyoto rats. After 1 h of restraint stress, NPY mRNA increased in the arcuate nucleus of the hypothalamus by 81%, but after 3 days (1 h day⁻¹), NPY mRNA increased by 40% in the arcuate nucleus and 50% in the medial amygdala (MeA). After chronic restraint (1 h day⁻¹ for 9–10 days), there was an upregulation of prepro-NPY mRNA and NPY itself in the amygdala but not in hypothalamic or cortical regions. Consequently, acute physical restraint, which promotes experimental anxiety, primarily suppressed NPY expression, but chronic physical restraint generally enhanced NPY signaling, especially in the amygdala. These results are believed to support an early hypothesis that suggests NPY may act to buffer the behavioral effects of stress-promoting signals.

The Effect of Exogenous Neuropeptide Y on Anxiety-Related Behaviors

NPY is consistently implicated in the pathogenesis of anxiety disorders, based on a significant number of findings that show NPY-induced anxiolytic activity in animal models widely used for the screening of anxiolytic compounds. NPY is reported to elicit anxiolytic-like effects in models of anxiety, including exploratory behavior-based tests such as the open field, elevated plus-maze, and light–dark compartment test, social interaction, punished responding tests, and fear-potentiated startle (see [Table 1](#)).

The open field test is often used to measure behavioral changes induced by anxiolytic or anxiogenic-like compounds in animal models. Anxiolytic drugs such as benzodiazepines and barbiturates increase the number of entries and time spent in the central area of the arena. Total crossings are presented as a measure of general locomotor activity in the arena. At higher doses, traditional anxiolytic drugs have significant sedative effects and suppress locomotor activity. Similarly, NPY causes dose-dependent suppression in open field activity when the intracerebroventricular (ICV) dose of NPY exceeds 5 µg. The significant effect of NPY on sedation in the open field led investigators to examine the potential anxiolytic properties of this peptide in the elevated plus-maze.

The elevated plus-maze is one of the most widely used tests for anxiety in animal models. The test is based on the conflict between the natural aversion of rodents for open spaces and the drive to explore a novel environment. Typically, the time spent on the open arms and the numbers of entries onto the open and closed arms of the maze are recorded. The percentage of open arm entries relative to the number of total arm entries is considered to be the superlative measure reflecting innate fearfulness. NPY,

administered ICV, decreased the preference for closed arm entries and increased the time spent on open arms. Higher doses of NPY (exceeding 2 nmol) suppressed entries into both closed and open arms, consistent with the sedative action of NPY observed at high doses in the open field.

A central mechanism involving the NPY Y₁ receptor subtype in the anxiolytic effect of NPY is supported by several pharmacological studies. For example, ICV administration of an antisense oligonucleotide targeted at Y₁ receptor mRNA attenuated NPY-induced anxiolytic-like effects in the elevated plus-maze and blocked the anxiolytic-like effect of NPY in the central nucleus of the amygdala (CeA) in the same test. This was confirmed in a study that demonstrated anxiolytic-like activity of the NPY, PYY, and the Y₁/Y₄/Y₅ agonist [Leu³¹, Pro³⁴]NPY but not the Y₂ agonist NPY(13–36). Further support for the Y₁ receptor was revealed with the anxiogenic-like effect of the Y₁ receptor antagonist BIBP3226. The Y₂-type receptor agonist, NPY(13–36), was later shown to induce anxiogenic-like effects in this model, in mice, when administered ICV.

More recently, there was an attempt to confirm the receptor subtype(s) involved in the anxiolytic/anxiogenic action of NPY as well as to determine which receptor(s) are involved in the sedative action of NPY. This study examined ICV injection of NPY as well as the specific receptor agonists for the Y₁ receptor ([D-His²⁶]NPY), Y₂ receptor (C2-NPY), and Y₅ receptor ([cPP(1–7), NPY(19–23), Ala³¹, Aib³², Gln³⁴]hPP) in the elevated plus-maze and open field tests. The results revealed that NPY and the Y₁ agonists had a dose-dependent anxiolytic-like effect in both behavioral tests. However, in contrast to NPY, which caused significant sedation in the open field test, the Y₁ agonist was without sedative effect. The Y₂ agonist showed neither anxiolytic-like nor sedative effects, and the Y₅ agonist showed anxiolytic-like activity in both behavioral tests and caused sedation in the same dose range as NPY in the open field test. The authors conclude that the anxiolytic-like effects of ICV-administered NPY in rats are mediated via both Y₁ and Y₅ receptors, whereas sedation is mediated via Y₅ receptors.

Additional support for the anxiolytic-like effect of NPY has been confirmed in the light–dark compartment test in which ICV NPY increased the number of transitions between the two compartments, a validated measure of anxiolytic activity in this test. Social interaction has also been pharmacologically validated as an experimental model of anxiety. The time spent in active social behavior, as well as locomotor activity, is recorded. NPY, when microinjected into the basolateral nucleus of the amygdala (BLA) and into

the caudal dorsolateral septum increases social interaction. Thus, NPY-induced anxiolysis in this paradigm of anxiety appears to be mediated by several brain regions. As in the elevated plus-maze, the involvement of the Y_1 receptor in social interaction is supported by blocking the anxiolytic-like effect of NPY with the intra-amygdalar injection of the selective Y_1 receptor antagonist BIBO3304. The role of the Y_5 receptor was also shown using [cPP(1–7),NPY(19–23),Ala³¹,Aib³²,Gln³⁴]hPP, a selective Y_5 receptor agonist. This agonist and the mixed Y_5/Y_2 agonist NPY(3–36) caused anxiolytic-like effects when injected into the BLA. The effect of NPY(3–36) was blocked by pretreatment with a purported Y_5 antagonist, Novartis 1 (synthesized by Eli Lilly). However, the Y_5 antagonist CGP71683A did not influence anxiety in any exploratory model of anxiety.

It has also been suggested that the Y_2 NPY receptor may mediate anxiogenic-like behaviors in the amygdala in this task. One study found a dose-dependent decrease in the time spent in social interaction when the Y_2 receptor agonist C2-NPY was directly injected into the BLA. However, the authors did not attempt to reverse the anxiogenic-like effects of this molecule with a selective Y_2 receptor antagonist, such as BIIE0246. The Y_2 receptor agonists may have an anxiogenic effect because the activation of the pre-synaptic Y_2 receptor may lead to decreased release of NPY and a subsequent decrease in Y_1 receptor activation. Overall, in the exploratory tests of anxiety including the open field, elevated plus-maze, and social interaction, NPY produces robust anxiolytic-like activity that is mediated through the Y_1 (and possibly Y_5) receptor subtypes, whereas the anxiogenic effects of NPY are mediated through Y_2 receptors.

Several versions of operant behavioral analysis for anxiety have been developed such as the Vogel conflict test and Geller–Seifter test, which are based on conflict of motivations rather than unconditioned exploratory models. In these tests, the subject experiences opposing and concomitant tendencies of desire (e.g., to obtain a reward) and of fear (avoidance of a potentially aversive stimulus). In the Vogel conflict test, water-deprived rodents are exposed to mild and intermittent electric shock via the spout of a water bottle when attempting to drink. In this test, treatment with anxiolytic drugs increases the number of accepted shocks during the punished phase. It has been shown that ICV NPY markedly increased the number of electric shocks accepted in this test. At the doses employed, NPY was reported not to affect pain sensitivity in a shock threshold test or to affect thirst. Thus, the anticonflict effects are considered to be related to a reduction of anxiety. In the Geller–Seifter conflict test, rats are trained to respond for a food

reward and are exposed to a modest electric shock during the conflict component of the procedure. The ICV injection of NPY consistently produces dose-dependent anticonflict/anxiolytic-like effects in the Geller–Seifter test, an established animal model of anxiety especially suitable for detecting the effects of benzodiazepine-like anxiolytics. The Y_1 receptor subtype is implicated in this test as well. Intra-amygdalar injection of [Leu³¹, Pro³⁴]NPY was shown to have anxiolytic-like effects. As in the exploratory models of anxiety, NPY can also induce anxiolysis in the conflict-based tests.

Startle is an adaptive response to acoustic stimuli that enables the individual to avoid, or reduce, the risk of an injury by a predator. In fear-potentiated startle, an acoustic stimulus is paired with an aversive intervention such as foot shock or air-puff, and after training, the stimulus alone is capable of elevating startle amplitude. As in the elevated plus-maze, ICV injections of NPY, PYY, and the $Y_1/Y_4/Y_5$ agonist [Leu³¹Pro³⁴]NPY inhibited fear-potentiated startle, whereas the Y_2 agonist NPY(13–36) had no effect. The Y_1 receptor is consistently indicated across diverse animal models of anxiety to mediate the anxiolytic-like activity of NPY. However, the Y_5 receptor cannot be ignored because [Leu³¹Pro³⁴]NPY does have some efficacy for the Y_5 receptor subtype. In addition, the Y_5 – Y_2 differentiating receptor agonist NPY(2–36) has shown anxiolytic-like activity in the elevated plus-maze and fear-potentiated startle.

Anxiety-like Behavior in Neuropeptide Y Receptor Knockout and Transgenic Animals

The development of the NPY transgenic rat has provided a unique opportunity to study the effects of this peptide on anxiety-related behaviors. In this transgenic rat model, there is central overexpression of prepro-NPY mRNA and NPY peptide in the CA1 region of the hippocampus and decreased Y_1 binding sites within the hippocampus (CA1, CA2, and dentate gyrus). Recently, NPY protein levels were also shown to be significantly higher in the paraventricular, suprachiasmatic, and supraoptic nuclei of the hypothalamus and tended to be increased in the arcuate nucleus in these rats. The transgenic animals were generated using a 14.5-kb fragment of the rat NPY genomic sequence that includes the normal intronic sequence elements and is flanked by a 5-kb 5' sequence thought to contain the major regulatory elements that normally control NPY expression. Consequently, the regulation of the NPY transgene is predicted to be similar to the regulation of endogenous

NPY. These molecular and neurochemical events led to an altered anxiety profile in NPY transgenic rats that included an insensitivity to restraint stress in the elevated plus-maze and an increase in the number of punished drinking events in the Vogel conflict test. The anxiolytic-like profile of the NPY transgenic rat was replicated in a study that showed NPY transgenic animals were resistant to acute physical restraint stress measured by the elevated-plus maze and displayed anxiolytic-like activity in the open field. The behavioral profile observed in the NPY transgenic rats was not associated with any significant changes in corticosterone levels before or following a stress challenge. This suggests a mechanism other than hypothalamic-pituitary-adrenal axis modulation and supports the role of the limbic system in the modulation of anxiety-related behaviors by NPY. This may be critically important and could distinguish NPY from other substances modulating stress-responses (although there are links between NPY and corticotropin releasing hormone, CRH).

The central role of the limbic system is also supported by recent studies involving Y_2 receptor subtype knockout ($Y_2^{-/-}$) mice. Mice deficient in the Y_2 receptor subtype displayed an anxiolytic-like phenotype in the elevated plus-maze and open field test. More recently, NPY $Y_2^{-/-}$ mice displayed increase preference for the central area of the open field when compared to wild-type control ($Y_2^{+/+}$) animals without changes in locomotor activity. These findings have been confirmed by an independent laboratory using the open field, elevated plus-maze, and light-dark compartment tests. These receptors are considered to be autoreceptors that provide negative feedback to NPY-ergic nerve terminals to modulate NPY release. Consequently, $Y_2^{-/-}$ mice are predicted to have increased endogenous peptide expression, analogous to the phenotype of NPY transgenic rats, which may contribute to the underlying mechanism responsible for anxiolytic-like behaviors regulated by NPY.

There is also evidence that NPY exerts anxiolytic-like effects through Y_1 receptors within the amygdala. The predicted anxiogenic-like phenotype of NPY Y_1 knockout mice is supported by a study that found significantly higher levels of territorial aggression in Y_1 knockout mice compared to control animals using established aggression paradigms.

Interestingly, NPY knockout ($NPY^{-/-}$) mice did not show a dramatic change in anxiety-like behavior in the elevated plus-maze. $NPY^{-/-}$ mice were found to have a significant increase in the amplitude response in the acoustic startle test, and they were less active in the central part of the open field, suggesting that these animals were more anxious. Overall, the results from NPY transgenic and knockout animals

provide compelling evidence for the role of NPY in the modulation of anxiety.

Clinical Evidence for Neuropeptide Y in Anxiety Disorders

In addition to the extensive preclinical data supporting NPY in the regulation of anxiety-like behaviors, a number of clinical studies have been published on the subject. In human subjects, there is a positive association between acute, uncontrollable psychological stress and robust increases in plasma levels of NPY. The increase in plasma NPY was positively correlated with increased cortisol and norepinephrine concentrations. A correlation between higher levels of stress-related NPY release and lower levels of subjective psychological distress was also found, supporting the possibility that NPY exhibits anxiolytic activity during stress in human subjects.

How Does Neuropeptide Y Regulate Emotionality?

The mechanistic action of NPY in anxiety-related behaviors is strongly associated with the amygdala. The amygdala is a key structure to the regulation of anxiety and expression of emotional responses to stress. Attention has been focused particularly on the basolateral complex (lateral, basolateral, and basomedial nuclei) and CeA. The amygdala contains NPY and significant levels of Y_1 and Y_2 receptor subtypes. These areas may be potential neural substrates to the behavioral effects of NPY on emotional regulation. NPY is also produced by neurons in the hippocampus with considerable expression of the Y_1 and Y_2 receptor subtype. In addition to the substantial evidence for the involvement of the amygdala and hippocampus, there is also evidence for the periaqueductal gray, septum, and locus coeruleus. However, the specific contribution of these anatomical regions requires further elucidation.

The interaction between CRH and NPY has been proposed as a means by which emotional behavior is regulated. In contrast to the anxiolytic-like effects of NPY, there is evidence that CRH has significant anxiogenic-like effects in animal models. For example, the ICV administration of CRH increases anxiety-like behavior in the elevated plus-maze, and CRH antagonists can block the behavioral effects of a stress challenge. The anxiogenic-like role of CRH has been confirmed in studies using CRH-overexpressing and CRH knockout mice. It has been shown that NPY can counteract the anxiogenic-like effect of CRH in the hippocampus, hypothalamus, locus coeruleus, periaqueductal gray, and septal nucleus. Moreover,

deletion of Y_2 receptors causes a 60% reduction in CRH mRNA expression that might contribute to the anxiolytic-like behavior of NPY Y_2 receptor knock-out mice. Thyroxine-treated adult animals displayed reduced anxiety in the motility box and elevated plus-maze, a reduction in the number of CRH-IR neurons in the CeA, and an increase in the number of NPY-IR neurons in nuclei of the basolateral complex of the amygdala.

It has also been proposed that NPY increases γ -aminobutyric acid (GABA) signaling to produce anxiolysis, analogous to many classes of anxiolytic drugs such as benzodiazepines. NPY is localized in GABAergic neurons in the amygdala, and there is evidence that NPY may directly modulate the activity of GABAergic neurons by stimulating Y_1 receptors. It has been shown that diazepam counteracts the anxiogenic effect of the Y_1 receptor antagonist BIBP3226, suggesting that the equilibrium between GABAergic and NPY-ergic neurotransmission may be important for the regulation of the emotional state in animal models. This conclusion is supported by a recent study that found chronic treatment with positive (anxiolytic) or negative (anxiogenic) regulators of GABA_A receptors modulate Y_1 receptor-mediated transmission in the amygdala. The authors suggest that the NPY Y_1 -mediated transmission and the GABAergic system may act together on the same postsynaptic target sites to decrease anxiety and that the Y_1 receptors might also play a role in controlling both the NPY and GABA presynaptic release.

However, it was recently shown that the anxiolytic-like effect produced by inhibiting the metabotropic glutamate receptor 5 (mGlu5) with the mGlu5 receptor antagonist MPEP is mediated by the NPY receptor and not by GABA. In order to determine the mechanism that contributes to the anxiolytic action of MPEP, the authors injected either the benzodiazepine antagonist flumazenil or the Y_1 receptor antagonist BIBO3304 into the BLA. Flumazenil antagonizes the effect of the several different classes of anxiolytic agents including the benzodiazepine diazepam, serotonergic agents, and noradrenergic ligands in animal models of anxiety through a GABA-mediated mechanism. However, the anxiolytic effects of MPEP were not changed by flumazenil; but they were abolished by BIBO3304 administration. The authors also found a decrease in NPY-IR neurons after three doses of MPEP administration, which suggests a decrease in NPY levels in the amygdala. The authors propose that the decrease in NPY levels may result from enhanced release of the peptide and that this release is responsible for the anxiolytic action of MPEP. Interestingly, the administration of metabotropic glutamate receptor antagonists into the hippocampus also produces

anxiolytic-like effects. NPY has been shown to inhibit glutamate release in the hippocampus, leading to the speculation that the anxiolytic-like effect of hippocampal NPY overexpression in NPY transgenic rats resembles the anxiolytic-like action of the metabotropic glutamate receptor antagonists. The interaction between glutamate acting via mGlu5 and NPY may represent a novel mechanism of anxiolytic action in the brain, independent of the traditional GABA-mediated benzodiazepine signaling.

Overall, these studies demonstrate that NPY and its receptor subtypes are significantly involved in the regulation of anxiety-like behaviors in both animal models and human subjects.

Neuropeptide Y and Vulnerability to Disease

Vulnerability to Depression

Depression is traditionally viewed as the manifestation of an inability to cope with various lifetime stressors that is presumably determined by genetics. Given the significance of NPY in the CNS as a modulator of anxiety, NPY may have a significant role in the etiology of depression and/or the effective reversal of symptoms. This theory is supported by preclinical data that consistently indicate a role for NPY in depression. For example, maternal deprivation is an animal model of depression/vulnerability to stress that posits that early life stress may cause changes in the CNS (e.g., hypothalamic-pituitary-adrenal dysregulation) that are associated with an increased risk of adult life depressive psychopathology. Using this model in rats for 3 h day⁻¹ during postnatal days 2–14, NPY levels were shown to be reduced in the hippocampus and striatum and increased in the hypothalamus. However, if lithium treatment was employed on days 50–83, the changes in NPY-IR induced by maternal deprivation were not observed in the hippocampus and striatum, whereas NPY levels were further increased in the hypothalamus. Consequently, early life stress has long-term effects on NPY levels in the CNS and may be a factor in the development of depression; possibly through an increased vulnerability to stress.

Additional evidence for NPY in depression is through the antidepressant-like properties of NPY. The Porsolt forced-swim test is widely used for the screening of potential antidepressant drugs. It has recently been shown that NPY displayed antidepressant-like activity in the rat forced-swim test. These results have since been confirmed in the mouse version of this test. ICV NPY administration significantly reduced immobility time in a dose-dependent manner,

as did [Leu³¹Pro³⁴]PYY. Attempts to determine the specific receptor subtype(s) involved has shown that BIBP3226 and BIBO3304 (selective Y₁ antagonists) and NPY(13–36) (a preferential Y₂ agonist) did not display any activity at the doses tested. However, pretreatment with BIBP3226 and BIBO3304 significantly blocked the anti-immobility effects of NPY. It is predicted that potentiation of NPY signaling at central postsynaptic receptors through Y₁ receptors is essential to reverse the behavioral characteristics of depression. The upregulation of NPY expression through Y₁ receptor activation may be advantageous for behavioral adaptation to stress-induced changes within the CNS. Consequently, a maladaptive response to stress may be the result of an intrinsic abnormal function of central NPY transmission that is characteristic of depressive states. Thus, NPY may be involved in the vulnerability to mood disorders through its endogenous modulation of emotional behavior.

Vulnerability to Alcoholism

Recent evidence suggests that NPY has a significant role in the neurobiological response to alcohol, including alcohol consumption, dependence, and withdrawal. NPY is beginning to emerge as an important neuromodulator in the etiology of alcoholism that is independent from the addictive and reinforcing properties of the traditional system and, instead, is strongly associated with innate emotionality. It is proposed that individuals with low innate levels of NPY and high basal levels of anxiety, or with low levels of NPY and increased anxiety caused by withdrawal, may drink increased amounts of alcohol in an attempt to reduce anxiety. There is evidence that supports this hypothesis from genetic lines of alcohol-preferring rats. For example, alcohol-preferring (P) rats have altered levels of NPY in several brain regions, including low levels of NPY in the amygdala compared to non-alcohol-preferring (NP) rats. P rats also have high basal levels of anxiety, which may predispose them to excessive alcohol drinking. The central infusion of NPY may reverse high alcohol drinking in P rats by reducing their high levels of anxiety. Studies in Wistar rats also indicate that animals with high levels of anxiety drink more alcohol than those with lower levels. Furthermore, because NPY is expressed at low levels in the amygdala following ethanol withdrawal, it is predicted that preventing this decrease in NPY expression might prevent subsequent withdrawal symptoms such as increased anxiety. Consequently, the motivational aspect of alcohol intake may be strongly tied to innate anxiety.

In summary, much evidence suggests a key role for NPY and its receptors in anxious behaviors. NPY and

congeners could also play a role in more chronic stressful situations that can possibly result in the development on depressive states or addictive behaviors.

Appetite-Regulating Neuropeptides and Stress

Glossary

*Hypophyseal
portal vessel
system*

A highly specialized blood vessel system that plays a vital role in the rapid transport of neuropeptides produced by the hypothalamic parvicellular neurons to target cells in the anterior pituitary gland. The hypophyseal portal system begins at the base of the hypothalamus with a group of capillaries (primary capillary plexus) that recombine into small portal veins, which pass down through the pituitary stalk into the anterior pituitary gland. Here they branch to form most of the anterior pituitary capillaries and sinusoids, which in turn drain into the systemic venous system. Almost all the blood supply to the anterior pituitary must first pass through the hypothalamo-hypophyseal portal system, arriving via the superior hypophyseal artery and leaving the anterior pituitary in the anterior hypophyseal vein.

*Hypothalamic-
pituitary-
adrenal (HPA)
axis*

One of the major physiological systems activated by stress; it consists of a hormonal cascade involving the hypothalamus of the brain, the anterior pituitary gland, and the cortex of the adrenal glands. The HPA axis is the humoral component of an integrated neural and endocrine system and results in the release of corticosteroid hormones from the adrenal glands. The major

*Median
eminence*

corticosteroids released during stress are the glucocorticoids, such as cortisol and corticosterone.

The median eminence is located at the base of the hypothalamus and is a region of confluence of neural and blood-borne messages where neuropeptides can be secreted from the terminals of neurons into the hypophyseal portal vessel system.

Neuropeptides

Peptides synthesized in, stored in, and released from neural tissue.

Stress

A complex physiological state that embodies a range of integrative physiological and behavioral processes that occur when there is a real or perceived threat to homeostasis.

There are numerous neuropeptides that are involved in the regulation of stress responses and released as effector molecules as a result of stress responses. Among the most widely researched stress-related neuropeptides are corticotropin releasing hormone (CRH) and arginine vasopressin (AVP), which regulate the hypothalamic-pituitary-adrenal (HPA) axis, and the opioid peptides, which have many functions. Oxytocin is a neuropeptide now recognized as a potentially important modulator of stress responses (**Figure 1**). Other neuropeptides, such as those involved in appetite regulation, can also influence the activity of the HPA axis during stress, although there is considerable variation in the scientific literature concerning the effects of these neuropeptides.

Stress-Related Functions of Corticotropin Releasing Hormone and Arginine Vasopressin

The key stress-related action of CRH and AVP is to act as hypophysiotropic hormones to stimulate the synthesis and secretion of adrenocorticotrophic hormone (ACTH) from the anterior pituitary gland (**Figure 1**).

Figure 1 Diagram of some of the key neuropeptides involved in stress-related functions. Corticotropin releasing hormone (CRH) and arginine vasopressin (AVP) are synthesized and stored in parvocellular neurons in the paraventricular nucleus of the hypothalamus (pPVN) and are released into the hypophyseal portal blood to stimulate the synthesis of peptides derived from proopiomelanocortin (POMC), including adrenocorticotrophic hormone (ACTH) and the opioid peptide β -endorphin, which are released into the systemic circulation. ACTH stimulates the synthesis of glucocorticoids, such as cortisol, from the adrenal cortex. Opioids such as enkephalin (ENK) and β -endorphin are synthesized in neurons in the brain and have many actions, including the modulation of stress responses. Neurons in the arcuate nucleus of the hypothalamus (ARC) that produce β -endorphin have important interactions with neurons in the pPVN that produce CRH and AVP. The opioid met-enkephalin (Met-enk) is released from the adrenal medulla due to sympathetic stimulation during stress. Oxytocin (OT) is stored in and released from neurons in the posterior pituitary as well as in the brain and acts to attenuate stress responses and reduce anxiety. Magnocellular neurons that synthesize OT and AVP have cell bodies in the magnocellular region of the PVN (mPVN) and supraoptic nucleus (SON) of the hypothalamus. There is also evidence that some neuropeptides best known for their actions in regulating appetite also influence the activity of stress systems, especially the hypothalamic-pituitary-adrenal axis.

The target endocrine cells in the anterior pituitary gland on which CRH and AVP act are called corticotropes. ACTH is released from corticotropes into the systemic circulation and stimulates the synthesis of the glucocorticoids by the adrenal glands. CRH and AVP also have various other physiological actions.

Corticotropin Releasing Hormone

The principal source of CRH is neurons located in the parvicellular division of the paraventricular nucleus of the hypothalamus, which project to the median eminence. CRH is synthesized in the cell bodies of these neurons, stored in the terminals and released into the hypophyseal portal blood. It is often considered that CRH is the primary stimulator of the release of ACTH, although it is clear that AVP from parvicellular neurons located in the paraventricular nucleus also plays a role. There may be species differences in the relative importance of these neuropeptides in stimulating the release of ACTH. Various stressful stimuli (stressors) activate the HPA axis, with the consequent release of CRH and AVP into the hypophyseal portal blood in a pulsatile pattern. Although the majority of CRH neurons projecting to the median eminence arise from the paraventricular nucleus, some CRH neurons from other hypothalamic nuclei project to the median eminence. CRH neurons also project to the brain stem and are found elsewhere, such as in limbic structures that are involved in processing sensory information and the regulation of the autonomic nervous system.

In addition to CRH, there are other CRH-like peptides, including urocortin I, urocortin II (or stresscopin-like peptide), and urocortin III (or stresscopin); at least two receptors (CRH-R1 and CRH-R2), and a CRH-binding protein. The CRH system is complex, and, in addition to the classic hypophysiotropic actions already described, it is important in regulating behavioral responses to stress. The activation of the HPA axis by CRH is mediated via CRH-R1, which is present in corticotropes. The binding of CRH to CRH-R1 stimulates the secretion of peptides derived from proopiomelanocortin (POMC) which, in addition to ACTH, includes β -endorphin, α -melanocyte-stimulating hormone, β -melanocyte-stimulating hormone, corticotropin-like intermediate peptide, γ -lipotropic hormone, and met-enkephalin.

Arginine Vasopressin

With the exception of the pig, all mammals studied synthesize AVP in the hypothalamus. In the pig, lysine is substituted for arginine, giving lysine vasopressin in this species. Within the hypothalamus, AVP is

synthesized in parvicellular neurons that project to the median eminence and magnocellular neurons that project to the posterior pituitary (Figure 1). The parvicellular neurons are located in the paraventricular nucleus and synthesize AVP in the cell bodies, store it in the terminals, and release it into the hypophyseal portal blood. There is an increase in AVP secretion during stress, and it travels by way of the hypophyseal portal system to the anterior pituitary gland to act synergistically with CRH to stimulate the release of ACTH from corticotropes. Some parvicellular neurons synthesize and store both CRH and AVP. The cell bodies of the magnocellular neurons that produce AVP are located predominantly in the supraoptic nucleus of the hypothalamus, and AVP is stored in the terminals in the posterior pituitary from which it is released directly into the systemic circulation. AVP released from the posterior pituitary is also known as antidiuretic hormone. Although this source of AVP is generally considered to function mainly to control fluid homeostasis and, in extreme stress, effect vasoconstriction, recent studies suggest that AVP from magnocellular neurons may also stimulate ACTH secretion.

AVP acts on three different receptors (V1a, V1b, and V2), which are expressed differently in various tissues and exert different actions. The actions of AVP to stimulate the release of ACTH are mediated by the V1b receptor. Many authors consider CRH, not AVP, to be the major stimulator of ACTH synthesis and secretion. Indeed, textbooks and scientific publications often fail to recognize the role of AVP as an ACTH secretagogue. Nevertheless, it is clear that AVP plays an important role in stimulating the secretion of ACTH during stress, although its relative importance may differ between species. For example, the majority of research in rats suggests that CRH is the major ACTH secretagogue, with AVP playing more of a permissive role, perhaps potentiating the effects of CRH. In contrast, in sheep there is evidence that AVP plays a major role in stimulating ACTH secretion, although other work has suggested that CRH is more important. It also appears likely that different stressors may influence the extent to which CRH and AVP stimulate ACTH secretion.

Regulation of Corticotropin Releasing Hormone and Arginine Vasopressin Secretion

The synthesis and secretion of CRH and AVP are influenced by both excitatory and inhibitory neural inputs from various regions of the brain that process information resulting from different stressors, negative feedback by glucocorticoids, and circadian rhythms. CRH and AVP neurons in the paraventricular nucleus

receive direct input from the limbic system and brain stem and indirect input from the cerebral cortex. Major excitatory input to CRH and AVP neurons arises from noradrenergic afferents of the brain stem (A_1 , A_2 , and A_6 noradrenergic cell groups), and there are reciprocal projections between CRH and AVP neurons in the paraventricular nucleus and neurons in the arcuate nucleus that produce POMC products, including the opioid β -endorphin. Glucocorticoids exert negative feedback by acting directly on the neurons that produce CRH and AVP and through other brain regions that have afferent inputs to the paraventricular nucleus. Glucocorticoids also act directly on pituitary corticotropes. The negative feedback actions of glucocorticoids regulating CRH and AVP synthesis are exerted via high-affinity mineralocorticoid receptors (MRs) and low-affinity glucocorticoid receptors (GRs). MRs are localized in the hippocampus and other regions of the limbic brain such as the lateral septum and amygdala, as well as hypothalamic sites. The glucocorticoids act via MRs to maintain basal activity. GRs have a more extensive distribution within the brain, being most abundant in the hypothalamus and in pituitary corticotropes, and are involved in the feedback actions of both basal and stress-induced levels of glucocorticoids. The circadian regulation of the HPA axis is illustrated by the circadian rhythms of CRH and AVP levels, which peak in the early morning and fall during the day in diurnal species. The negative feedback effects of glucocorticoids also vary in a circadian fashion.

Opioids

The opioid peptides and their receptors are distributed widely in the body. This distribution includes the central, peripheral, and autonomic nervous systems as well as several endocrine tissues and various target organs. The opioids are involved in a broad range of functions, including acting as neuropeptides to regulate stress responses. There are three classes of opioids: β -endorphin, the enkephalins (met-enkephalin and leu-enkephalin), and the dynorphins. It is often considered that the affinity of β -endorphin, the enkephalins, and dynorphins is highest for the μ -, δ -, and κ -opioid receptor subtypes, respectively. However, it is also apparent that opioids can bind to more than one receptor subtype.

Peptides Derived from Proopiomelanocortin

As previously indicated, a large number of peptides are derived from processing POMC. This includes the opioid β -endorphin. Peptides derived from POMC

are found in the brain, anterior pituitary gland, gut, thyroid, thymus, adrenal medulla, pancreas, spleen, macrophages, placenta, testes, and ovaries. There is a wide distribution of β -endorphin within the brain, with the highest concentrations occurring in the medial hypothalamus and arcuate nucleus. Acting as a neuropeptide and neurotransmitter, β -endorphin is involved in a range of stress-related functions, including the modulation of CRH and AVP neurons in the paraventricular nucleus. Furthermore, during stress, the secretion of β -endorphin from the anterior pituitary gland increases in parallel with ACTH. The physiological significance of this is not known, although it is possible that this source of β -endorphin contributes to some of the known actions of β -endorphin during stress. These actions include analgesia and the regulation of blood glucose concentrations and the immune system.

Peptides Derived from Pro-Enkephalin

Pro-enkephalin (also referred to as pro-enkephalin A) is the major biological source of met-enkephalin and is a source of leu-enkephalin. Met-enkephalin-containing peptides are present in the central nervous system, adrenal medulla, gastrointestinal tract, and many other tissues. The neurons that synthesize met-enkephalin are extensively distributed throughout the central nervous system, making enkephalin the most widely distributed opioid in the brain. Pro-enkephalin neurons exist throughout the hypothalamus, including the paraventricular nucleus. The chromaffin cells of the adrenal medulla also synthesize pro-enkephalin. Met-enkephalin is often cosecreted with the catecholamines from the adrenal medulla into the peripheral circulation during stress. The biological significance of this is also unknown.

Peptides Derived from Pro-Dynorphin

Pro-dynorphin (also referred to as pro-enkephalin B) can be processed to produce dynorphin A, dynorphin B, α -neoendorphin, and β -neoendorphin. Pro-dynorphin is found in many parts of the central nervous system, including the hypothalamus, hippocampus, brain stem, amygdala, and gastrointestinal tract. The neurons that produce dynorphins in the hypothalamus are mainly located in the supraoptic nucleus and paraventricular nucleus. Dynorphins have greatest affinity for the κ -opioid receptor. Less is known about the dynorphins than the other classes of opioids, although it is apparent that they have many different physiological actions depending on their site of production. These actions include influencing the pattern of electrical activity

of magnocellular neurons that produce AVP and negative feedback regulation of oxytocin secretion.

Stress-Related Functions of Opioids

Opioids exert a diverse range of stress-related actions. In particular, opioids act to attenuate or terminate stress responses. This modulatory influence on stress responses may provide a mechanism for preventing the detrimental effects of sustained or chronic stress. Specifically, opioids can inhibit the activity of the HPA axis. At least part of this mechanism involves the inhibition of the synthesis of CRH and, possibly, AVP. The reciprocal interactions between CRH and AVP neurons in the paraventricular nucleus and β -endorphin neurons in the arcuate nucleus are clearly important for this modulatory effect (Figure 1). Further, opioids regulate sympathetic, cardiovascular, and respiratory neural control systems and are involved in the regulation of pain, reinforcement and reward, the release of neurotransmitters, and other autonomic and neuroendocrine functions.

Opioids are involved in the control of pain and play a major role in suppressing the perception of pain (i.e., analgesia). In particular, opioids are mediators of stress-induced analgesia. The phenomenon of stress-induced analgesia is well known. There are many accounts of people being unaware of pain during a stressful experience. The origin of pain is normally at the site of intense stimulation or tissue damage, causing the discharge of impulses in a specialized set of nerve endings (nociceptors). The intensity of the excitation is regulated by local chemical signals that are released when the tissue is damaged. These include the opioids. Information about painful stimulation is carried as impulses in afferent nerve fibers that synapse in the dorsal horn of the spinal cord. Postsynaptic neurons convey the nociceptive information to the brain. Transmission at these synapses is modulated by locally released neurotransmitters, including opioids. The perception of the pain can be altered by modulation in the dorsal horn. The brain influences the processing of nociceptive input in the spinal cord, partly by activating opioid interneurons in the dorsal horn. It seems that both opioids produced in the brain and circulating opioids are involved in the induction of analgesia, with the source of the opioids that induces the analgesia varying with the type of stressor.

Oxytocin and Stress

Oxytocin is synthesized in cell bodies of magnocellular neurons located principally in the paraventricular

nucleus of the hypothalamus, is stored in the terminals of these neurons in the posterior pituitary, and is released from there into the peripheral circulation (Figure 1). Oxytocin is also synthesized in neurons that are widely distributed within the central nervous system. The actions of oxytocin are mediated via specific high-affinity receptors that are distributed both peripherally and in many forebrain areas, including regions of the hippocampus and amygdala, bed nuclei of the stria terminalis, ventrolateral septum, and several hypothalamic nuclei. Thus, oxytocin has both peripheral and central actions, some of which concern the regulation of stress responses. The classic peripheral actions of oxytocin are to cause contraction of the myoepithelial cells of the mammary glands to stimulate milk let-down and to stimulate the myometrium of the uterus during parturition. Oxytocin also has stress-related effects, and circulating concentrations of oxytocin increase in response to some, but not all, types of stress. Oxytocin can act within the brain to reduce the responsiveness of the HPA axis to stress with reduced cortisol secretion due, at least in part, to a reduction in CRH synthesis. Oxytocin can also reduce blood pressure, increase tolerance to pain, and reduce anxiety. Oxytocin facilitates mother–infant interactions and tends to facilitate behaviors that oppose fight-or-flight behavioral responses to stress. Lactating females (in which oxytocin levels are elevated) generally display attenuated responses to stress, and although a number of different mechanisms may be involved, oxytocin is likely to play a role. Generally, oxytocin is not considered to readily cross the blood–brain barrier although this dogma has recently been challenged. It is difficult to know whether the actions of oxytocin to dampen stress responses are due to central and/or peripheral effects.

Appetite-Regulating Neuropeptides and Stress

Various neuropeptides that regulate appetite can affect the activity of the HPA axis in response to stress. These include orexin, neuropeptide Y (NPY), agouti-related protein, and cocaine and amphetamine-regulated transcript (CART).

The peptides orexin-A and orexin-B are produced in the hypothalamus and can modulate the activity of the HPA axis, both centrally and peripherally. Orexin receptors are widely distributed and are found in the paraventricular nucleus, median eminence, pituitary corticotropes, adrenal cortex, and adrenal medulla. These neuropeptides can stimulate the release of

CRH and AVP as well as having direct stimulatory effects on the adrenal cortex.

NPY may mediate the excitatory effects of orexins. Certainly NPY can influence the activity of the HPA axis, although it is not clear how because NPY has been found to both inhibit and stimulate the release of CRH. The synthesis of NPY increases in the arcuate nucleus and hilus of the dentate gyrus following restraint stress in rats.

Agouti-related protein is an appetite stimulant that is coexpressed in the arcuate nucleus with NPY, and there is differential regulation of this neuropeptide in relation to stress. For example, foot shocks in rats decreased agouti-related protein synthesis and increased NPY synthesis.

CART is synthesized in neurons in various hypothalamic structures, including the paraventricular and arcuate nuclei. Glucocorticoids can influence the synthesis of CART, and CART can act within the paraventricular nucleus to activate the HPA axis.

Neurosis

D J Lynn

Thomas Jefferson University, Philadelphia, PA, USA

© 2007 Published by Elsevier Inc.

The term neurosis was used officially with confidence and authority in American psychiatry as recently as 1980, but, at least since the 1994 *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV), it has been officially abandoned. For official American psychiatry, it is now of primarily historical interest. To understand the evolution of the use of this term, and the related controversy, is to understand a great deal about the recent changes within American psychiatry.

The Scottish Physician William Cullen (1710–1790) introduced the term in his *First Lines of the Practice of Physic*, which first appeared in English in 1777. Cullen used the term neuroses to refer to one of four general categories of illnesses. The other three

were pyrexiae (febrile diseases), cachexiae (diseases resulting from bad habits), and locales (diseases consisting of local lesions). The category Cullen named neuroses included all conditions of the central nervous system not related to fever or focal lesions.

During the nineteenth century, the term evolved into psychoneuroses, which Richard von Kraft-Ebing defined in 1872 as mental illnesses in cases in which the brain was normal.

Neuroses were at the heart of the psychoanalytic writings of Sigmund Freud (1856–1939). He was most concerned with psychoneuroses, which he distinguished from actual neuroses by their etiologies. For Freud, psychoneuroses were caused by unconscious conflicts, generally of a sexual nature, with roots in childhood. Actual neuroses were caused by current factors within the patient's awareness. In American psychiatry in the mid-twentieth century, the influence of Freud's writings and the writings of his followers was extremely strong, and in DSM-II,

the term neurosis was used pervasively. In general in this era, the unconscious conflict believed to be causing the manifest neurotic symptoms attracted much more attention than the symptoms themselves. For any particular patient, the symptoms were seen as a product of, and in some sense a solution to, that patient's specific unconscious conflict. For psychoanalytically oriented psychiatrists, attention to the symptoms was important not for the purposes of arriving at a prognosis or conducting research but for delineating, and interpreting for the patient, the unconscious conflict.

DSM-III, published in 1980, was a systematic attempt to redirect attention to observable and quantifiable symptoms. Disorders were classified in a descriptive manner; the neuroses, so prominent in DSM-II, were discarded, and the term neurosis was relegated to parentheses. The authors stated that "at the present time, there is no consensus in our field as to how to define 'neurosis'" American Psychiatric Association (1980: 9). Some psychiatrists were using the term in a descriptive sense to denote a pattern of observable symptoms; others used it to designate a psychogenic etiology. DSM-III used an atheoretical approach concerning the disorders formerly termed neuroses for two stated reasons: (1) the etiology of these disorders was declared to be unknown and (2) the goal was to arrive at a system of classification that could be used by clinicians whether or not they agreed with particular theories of etiology. The editors suggested that the term neurotic disorder could be used, but only descriptively (to refer to an observable symptom pattern), and that, whenever psychiatrists wanted to convey an etiology based in unconscious conflict, the term neurotic process should be used. DSM-III-R (1987) basically continued the use of its predecessor, but DSM-IV (1994) contains no mention of the term neurosis.

For some psychoanalytic psychiatrists, these developments led to consequences that were seen as unfor-

tunate. As Glen Gabbard put it: "although this classification accommodates the recent biological research delineating different kinds of anxiety, it also encourages clinicians to think about anxiety as an *illness* rather than as an overdetermined *symptom* of unconscious conflict".

What Is Neuroticism, and Is It Genetic?

Which Regions of the Genome Are Linked to Neuroticism?

Have Association Studies Identified Any Genes Associated with Neuroticism?

Roles of Candidate Genes in Stress

Glossary

<i>Complex traits</i>	Phenotypes governed by variation in many genes; often continuously and/or normally distributed. The trait does not segregate in the population following any obvious patterns. Environmental influences often account for as much as, or more than, genetic influences.
<i>Genome</i>	The set of all genes for a particular organism. In humans this includes both nuclear and mitochondrial DNA sequences.
<i>5-HTTLPR</i>	Gene polymorphism in the 5'-promoter region of the gene encoding the serotonin (5-hydroxytryptamine; 5-HT) transporter (5-HTT) that has been implicated in susceptibility to life events/stressors.
<i>LOD score</i>	Logarithm of the odds score favoring linkage. The higher the score, the greater the evidence for linkage.
<i>Mendelian or simple traits</i>	Phenotypes governed by a single major locus or gene and hence the traits can be seen to segregate in the population following obvious additive, dominant, or recessive patterns.
<i>Phenotype</i>	Any observable and measurable characteristic of an organism produced by genetic and/or environmental influences.
<i>Quantitative trait locus (QTL)</i>	A locus implicated in genetic variation that causes a change in a continuous phenotype.

What Is Neuroticism, and Is It Genetic?

Neuroticism is a unique dimensional measure of personality thought to capture emotional stability and a temperamental sensitivity to negative stimuli. Indeed, it is a widely agreed upon higher order factor in many different personality constructs. Currently, three measures of personality are commonly used in genetic research: Eysenck's Personality Questionnaire, Cloninger's Temperament and Character Inventory, and

the Neuroticism Extraversion Openness (NEO) personality inventory. For Cloninger's measure of harm avoidance (HA) and Eysenck's measure of neuroticism (EPQ-N), there is some evidence that these different personality constructs are influenced by similar genetic and environmental variables. In the case of the EPQ-N, high scorers are conceived to be overly emotional, react strongly to stimuli, and find it difficult to recover after an emotionally stimulating experience, while low scorers are conceived to be calm, even tempered, and emotionally controlled. The genetic influence on neuroticism and harm avoidance has been widely assessed, and the estimates of heritability are 40–60% of the phenotypic variance. The EPQ-N is known to overlap genetically with many internalizing disorders, such as major depression, panic disorder, and generalized anxiety disorder, and because of this, neuroticism has been used in psychiatric genetic research to identify the genetic variation causing individual differences in the susceptibility to both depression and anxiety.

Which Regions of the Genome Are Linked to Neuroticism?

Traditionally, there have been two statistical approaches to relate variation of the genome to a phenotype of interest, known as linkage mapping and association mapping. Linkage mapping has played a huge historical role in the gene mapping of Mendelian traits. In essence, the method relies on the phenomenon of allele sharing among relatives. For example, monozygotic twins share 100% of their genome, while siblings and dizygotic twins should share only 50% – on average – of their genome. To illustrate this, if two siblings are both highly neurotic, then genetic variation at a region of the genome that is truly linked to neuroticism would be expected to be shared by the siblings. If such a phenomenon is observed in more siblings than would be expected by chance, this region of the genome is declared linked to neuroticism. Linkage is a useful approach for coarse mapping, as it identifies large regions of the genome as being linked to the phenotype, but this is also a disadvantage, as large regions can contain hundreds of candidate genes. As this analysis cannot distinguish which gene or genetic variant is responsible for the linkage, it is usual after the identification of a region to perform the finer association mapping approach to localize more precisely the disease gene (see next section).

To date, there have been seven linkage studies examining a neuroticism-like phenotype. The first

reported study, undertaken by Cloninger and colleagues, examined HA and observed significant linkage to the long (p) arm of chromosome 8. Additive and nonadditive interaction of the chromosome 8 peak with other loci suggested significant interaction with chromosomes 11, 18, 20, and 21. A subsequent study assessed selected regions of the genome for linkage to HA and also found linkage in an overlapping region of chromosome 8. It is not possible, however, to deduce that the same sequence variant(s) is responsible for the linkage in both these studies. Further fine mapping of the chromosome 8p region in the same sample refined the region to one around the neuroregulin gene (*NRG1*), which has been implicated in schizophrenia susceptibility. The *NRG1* protein is involved in signaling based on the glutamate neurotransmitter and plays a central role in neural development. Interestingly, neuroticism and HA have been reported as elevated in first-degree relatives of schizophrenics and schizotypal individuals. A re-analysis of the original data set, using a novel method, reproduced the evidence for linkage to the chromosome 8p markers. As these four studies are derived from only two samples, it is difficult to decide if a true quantitative trait locus (QTL) actually resides on chromosome 8p. The possibility that *NRG1* is a candidate for harm avoidance is intriguing, but the gene needs to be extensively examined in multiple samples before any robust conclusion can be drawn.

The first published linkage analysis of the EPQ-N was carried out by Fullerton and colleagues in a UK selected sibling sample. The main findings were QTLs on chromosomes 1, 4, 7, 12, and 13. Further evidence was presented that these loci for neuroticism might be gender specific: the QTLs on chromosomes 1, 12, and 13 appeared to be female specific, while a QTL on chromosome 8, which was not found to be genome-wide significant in the complete sample analysis, appeared to be male specific. It is interesting to note that the chromosome 8 locus is in close proximity to the chromosome 8p locus identified in HA. The second published study used a composite index of four self-report measures of anxiety and depression, including Eysenck's measure of neuroticism in a large UK-based sibship sample. As opposed to only examining Eysenck's neuroticism measure, Nash and colleagues used structural equation modeling on the four self-report measures to derive a phenotypic composite index of the shared genetic liability to both depression and anxiety. While no significant findings were obtained, linkage peaks closely approaching significance were obtained on chromosomes 1p and 6p for both the composite index and neuroticism, with a high correspondence of results between the two phenotypes. Splitting the sample by gender led to the identification of a linkage peak for females on

chromosome 12, while also indicating female specificity of the chromosome 1 peak and male specificity of the chromosome 6 peak. The most recent linkage publication on EPQ-N was performed in a New Zealand sample. While no peak reached statistical significance, a suggestive finding of linkage was obtained on chromosome 12, with nominal findings of linkages on chromosomes 1, 3, 6, 11, 15, and 17. Comparing the results from these three studies indicates a low correspondence between the results. There is possible overlap on chromosomes 1 and 12. The peak on chromosome 12 is potentially exciting, as this also overlaps with linkage peaks from both unipolar and bipolar depression. Indeed, as discussed later, variants of a gene within this peak have recently been observed to segregate with major depression and might also be associated with individual variation in neuroticism.

Similarly, comparisons between all the studies on neuroticism and harm avoidance show only slight correspondence. This is not unexpected, unless a major locus (responsible for >20% phenotypic variance) was involved. While linkage is a powerful method for simple traits with genes of major effect, its poor ability to reliably detect loci with a small phenotypic effect relegates the method to a preliminary tool providing genomic targets on which to focus fine mapping projects. Its contributions in this field at best provide suggestive evidence that chromosomes 1, 8, and 12 might harbor genetic variants that are associated with neuroticism/harm avoidance.

Have Association Studies Identified Any Genes Associated with Neuroticism?

Association mapping has historically been employed to evaluate the potential contribution of specified candidate genes, or as a follow-up, fine mapping tool to linkage analysis. Due to technological advances in speed and the reduction in expense in measuring differences in the genome, whole genome association mapping will eventually become the predominant mapping approach. The simplest version of association mapping is in case control studies of unrelated individuals and essentially examines whether or not there is a correlation between the genetic variation and the phenotype. This basic approach suffers from the fact that a much larger number of sequence variants need to be measured to capture adequately the effective genetic variation compared to linkage analysis. Nevertheless, the increased ability to detect small changes is the most attractive feature of this approach to gene mapping.

Function-Based Candidate Genes

Perhaps the biggest shift in thinking with respect to psychiatric and personality genetics has been the

reduction in the expected effect size of a single genetic variant. While initial expectations were that a single genetic variant might account for around 10% of the phenotypic variance, it is now thought that 1%, or much less, is a more realistic expectation for single variants. Commonly, sample sizes are inadequate to detect such effects reliably. To tackle this problem, meta-analytic techniques can be implemented that use the results of multiple studies to estimate reliably the effect sizes and significance of genetic variants. In the only published meta-analysis of genetic polymorphisms in personality, Munafo and colleagues examined commonly researched genetic variants in the serotonin transporter (*SLC6A4*) and various dopamine genes (*DRD4*, *DRD2*, *DRD3*, and *DAT1*). Of all the results, the only significant meta-analytic association was between a polymorphism in *SLC6A4* and neurotic/avoidant traits.

Current evidence indicates that the serotonin transporter gene (*SLC6A4*), located on the long arm of chromosome 17 (17q), is probably the only gene that can be considered associated with neuroticism, albeit only weakly. The mature protein of this gene transports serotonin from the synaptic cleft back into the presynaptic neuron for reuse and is responsible for the quantity of serotonin in the synaptic cleft. A sequence variant, known as 5-HTTLPR, is present in either a short or long form in a region of the gene called the promoter, which regulates the rate at which the mRNA of the gene is made. The first study of this variant identified an association of the number of short variants with an increase in neuroticism. Subsequently, there have been many attempts at replicating this finding with varying degrees of success. To address this issue, there have been several meta-analyses of the many findings, with a general consensus supporting a small but positive association. Recently, Caspi and colleagues observed that the relationship of stressful life events and depression was mediated by 5-HTTLPR, such that individuals with two long alleles were unchanged in their risk to depression as life events increased, while the risk of depression was increased in those carrying one or more short alleles. This finding has subsequently been replicated for depression, but comprehensive studies looking only at neuroticism and 5-HTTLPR have found no mediation of the variant on the effect that life events have on neuroticism. It is highly probable that 5-HTTLPR and neuroticism are weakly associated; what is unknown, and a source of current interest, is the developmental mechanisms that 5-HTTLPR affects, which lead to its association with individual differences in neuroticism.

A more recent line of research has been driven by theories of aberrant neuronal apoptosis and

neurogenesis in major depression. Based on such theories, some research has been carried out on genetic variants known to affect these mechanisms. The most studied of these is the brain-derived neurotrophic factor gene (*BDNF*), located on chromosome 11p. The BDNF protein has a well-documented role in neuronal development, survival, and plasticity, making it an attractive candidate for many psychiatric disorders. Indeed, variants in the gene have been associated with disorders such as obsessive-compulsive disorder, bipolar disorder, and major depressive disorder. Because neuroticism is genetically related to major depression and is a phenotypic marker for vulnerability to depression, genetic variants in the *BDNF* gene have been examined for their relationship with neuroticism. The original association with this gene examined a single nucleotide polymorphism that changes the 66th amino acid from a valine to a methionine and its association with neuroticism as measured by the NEO personality scale. This study found an apparently strong finding, with those individuals carrying the Met/Met genotype having substantially lower neuroticism scores than the rest of the sample. Subsequent follow-up studies using the NEO personality scale or HA have not found such strong evidence, and a recent comprehensive study examining the EPQ-N found no evidence for an association. It appears that although *BDNF* might be a plausible candidate gene for neuroticism, the data simply do not currently support this. As these studies have focused on only one variant in the gene, it is plausible that other variants in the gene are associated with neuroticism.

Position-Based Candidate Genes

Despite the promising leads from linkage studies, no positional candidates have emerged so far, but there have been some possible leads from related scientific fields. *RGS2*, or regulator of G-protein signaling 2, is a positional candidate gene from linkage studies that examined emotionality in mice. This gene is located on mouse chromosome 1 and corresponds to a region on human chromosome 1. Whether this gene is responsible for the linkage signal seen on this chromosome has not yet been established. Nevertheless, there have been reports that variants in the human version of this gene might be associated with agoraphobia. Another possible gene is *APAF1*, apoptosis protease activating factor 1, involved in the apoptosis pathway. This gene, located at 12q, was recently associated with major depression in Utah families. Functional studies indicated that only those variants that segregated with major depression had a functional effect on the apoptosis pathway. Given the genetic

relationship between the EPQ-N and major depression, it is possible that *APAF1* also contributes to individual differences in neuroticism. This gene is located within the chromosome 12 linkage peak identified in two studies of neuroticism, as mentioned previously, lending weight to the suggestion that genetic variation in this gene might be associated with neuroticism.

Roles of Candidate Genes in Stress

There are a number of possible mechanisms that might explain the relationship of the aforementioned candidate genes with stress. Upon being stressed, the body enters into various response patterns, including at the molecular level an increase in firing from serotonergic neurons. As the role of the serotonin transporter is the reuptake of serotonin from the synaptic cleft, the rate at which new transporter can be made might affect the rate at which the biochemical system regains homeostasis. Because the short, low-activity 5-HTTLPR allele carriers produce less mRNA, these individuals might return to their biochemical baseline slower than long allele homozygotes. This delay might then leave these individuals more susceptible to the detrimental effects of stress. Another aspect of these detrimental effects is the neuronal toxicity of glucocorticoids, which are released as a negative feedback mechanism during response to a stressor, and it is known that glucocorticoids are capable of damaging hippocampal neurons. The rate and impact of this damage might be mediated by both BDNF and *APAF1*. BDNF is involved in neuronal survival, while *APAF1* is involved in cell death. The functional variation that has been identified for these genes might cause some individuals to be more resilient to the toxic effects of stress, while making others more vulnerable. This model suggests that individuals who carry the S allele of 5-HTTLPR, who are homozygous for the BDNF Met allele, and who also have the apoptosis rate-increasing alleles of *APAF1* may be more vulnerable to the detrimental effects of stress.

Personality and Neuroticism

Animal Models of Emotionality

Genetic Mapping in Rodents

Comparisons between Rodents and Humans

Glossary

<i>Allele</i>	An alternative form of a genetic locus; a single allele for each locus is inherited separately from each parent.
<i>Backcross</i>	A cross between one animal type that is heterozygous for alleles obtained from two parental strains and a second animal type from one of those parental strains. The term is often used by itself to describe the two-generation breeding protocol of outcross followed by a backcross that is used frequently in linkage analysis.
<i>F1</i>	The first filial generation; the offspring resulting from the first experimental crossing of animals. The progeny produced by intercrossing F1 individuals are referred to as F2 individuals.
<i>Heterozygous</i>	Having two different alleles at a given locus.
<i>Homozygous</i>	Having two identical alleles at a given locus.
<i>Inbred strain</i>	Animals that result from the process of at least 20 sequential generations of brother–sister matings. This process is called inbreeding.
<i>Intercross</i>	A cross between two animals that have the same heterozygous genotype at designated loci, for example, between sibling F1 hybrids that were derived from an outcross between two inbred strains.
<i>Outcross</i>	A cross between genetically unrelated animals.
<i>Neuroticism</i>	A personality trait dimension that refers to emotionality, emotional instability, and stress reactivity.
<i>Quantitative trait locus (QTL)</i>	A locus that affects a quantitative trait.
<i>Syntetic genes</i>	Genes thought to reside on the same chromosome.

Personality and Neuroticism

Broad behavioral traits underlie variation in human personality, and there is general consensus that certain of these relate to individual differences in response to stress and in vulnerability to anxiety and depression in humans. Behavioral evidence of anxiety-related traits has been observed from amphibians to rodents and higher mammals. In humans, these traits have been described variously as neuroticism, trait anxiety, and harm avoidance, and there is now general agreement that any adequate trait model of personality must include a broad trait related to vulnerability to anxiety- and depression-related disorders, representing an evolutionarily conserved capacity for fear and anxiety.

The notion that a single underlying risk factor underlies vulnerability to both anxiety- and depression-related disorders is supported by evidence from twin studies in humans that these disorders share a common genetic basis. Moreover, numerous studies have arrived at similar estimates of the contribution of genetic variance to variation in trait neuroticism, with additive genetic variance estimated at approximately 30% and nonadditive variance at approximately 15%. This has led to attempts to better understand the molecular genetic architecture of trait neuroticism in humans likely to result from multiple low-magnitude genetic effects and their interactions, both with other genetic loci and environmental factors; however, this research has generally yielded disappointing and inconsistent results.

Better progress has been made in studies of animal models of emotionality, which offer several attributes useful in genetic research, including short gestation, early puberty, and large litters, as well as a greater degree of experimental control by means of directed mating and environmental control, all of which are valuable when attempting to map the genetic architecture of these traits.

Animal Models of Emotionality

Defining an animal's temperament is not easy, and operational definitions typically require the animal to show a consistent pattern of response to a behavioral task or series of tasks. For example, an animal model of emotionality might be operationally defined as the length of time it takes an animal to emerge into an aversive or threatening environment. This obviously requires relatively strong assumptions regarding the

Table 1 Animal tests of emotionality

<i>Unconditioned responses</i>	
Open-field arena	Activity, defecation, thigmotaxis
Elevated plus-maze	Ratio of entries to open and closed arms
Light-dark box	Emergence time
Hyponeophagia	Latency to start eating
Holeboard	Head dipping
Social interaction	Frequency of social interaction in a novel environment
<i>Conditioned responses</i>	
Two-way avoidance conditioning	Rate of acquisition of response
Acoustic startle	Contraction in response to loud noise
Foot shock-induced freezing	Contraction in response to conditioned stimulus
Fear-potentiated startle	Contraction in response to loud noise in conjunction with conditioned stimulus
Geller-Seifter	Frequency of conditioned response coincidental to an electrical shock
Vogel conflict	Frequency of conditioned licking coincidental to an electrical shock

extent to which this operational definition is an accurate analog of the same construct in humans. The majority of animal studies of emotionality have employed rodent models (i.e., mouse or rat). [Table 1](#) lists a number of tests of emotionality in animals, divided into measures that depend on unconditioned (ethological) and conditioned responses. Conditioned responses have the advantage of offering much more experimental control. These measures are founded on principles of avoidance, autonomic activation, and behavioral inhibition (i.e., the discontinuation of species-typical behaviors such as exploration).

The open-field apparatus is one widely used paradigm and consists of a circular, white, brightly lit, and fully enclosed arena that allows remote monitoring of behavior over a short period. Unfortunately, many of these tests rely on features unrelated to the trait of interest (i.e., emotionality). For example, many depend in part on the basal activity level of the animal, which may be a potential confound. A potential solution to this problem is outlined here.

Genetic Mapping in Rodents

The mouse genome is well characterized, comprising approximately 22 000 predicted genes, of which approximately 80% have an identifiable human ortholog. Inbred rodent strains exhibit substantial variability in emotionality, and these differences can be exploited for the purposes of quantitative trait mapping. Crosses between inbred strains of rodents are frequently used to map the quantitative trait loci (QTL) that give rise to the genetic component of variation in behavioral traits such as emotionality. The basic experimental design is the analysis of association between genotypic and phenotypic variation in a cross between two inbred strains of rodents (usually, but not necessarily, with contrasting emotionality

phenotypes). Several strategies exist, but in the most widely used either the offspring of the cross (the F1 generation) are mated to produce a F2 intercross or the offspring are backcrossed to either of the parental strains. Molecular genetic markers are then used to determine which chromosomal segments segregate with the trait (i.e., which chromosomal regions are shared by animals that are phenotypically similar for the trait of interest). Over the past 10 years, QTLs putatively related to emotionality have been identified on a number of chromosomes, although the molecular nature of these remains unclear.

One problem is that genetic mapping identifies a potential functional variant, rather than a gene, and functionally important variants that affect gene expression may lie some distance away from a gene or even in the location of an unrelated gene. Another problem is that this experimental design offers only a limited number of recombinants in a single generation (typically, between one and two), so that the resolution to map a specific locus is limited and may identify regions that can still contain hundreds or perhaps thousands of genes.

It is possible to remedy the problem of limited mapping resolution by mapping loci in genetically heterogeneous stocks of rodents that are generated from multiple (usually eight) inbred strains that have been successively intercrossed for maximal diversity and maintained over multiple generations through a program of pseudorandom mating. Because these animals are several generations removed from the original progenitor strains, this offers the potential of mapping a QTL to a limited number of genes, although this requires a substantial increase in marker density and the analysis is considerably more complex in this case. At present, this is most economical once broad chromosomal regions have been

Figure 1 Quantitative trait loci that influence behavior in the De Fries strain of mice. a, Genome scan for two measures that control for putative confounds (home cage activity and tail hang); b, genome scan for two measures of emotionality (EPM open arm entries and SQ open arm entries); c, genome scan for three measures of emotionality (open field activity, LD transitions, and MR latency to emerge). Chromosomes that harbor significant genetic effects are shown as numbers on each panel. EPM, elevated plus-maze; SQ, square maze; LD, light–dark box; MR, mirror chamber. From Flint, J. (2004), The genetic basis of neuroticism, *Neuroscience Biobehavioral Review* 28, 307–316. © 2004 with permission from Elsevier.

identified, thereby limiting the number of markers required for QTL localization.

There also exists a potential solution to the problem of ensuring that the identification of loci related to emotionality in rodent models is specific to this trait. This is to attempt to identify chromosomal regions that influence multiple measures of emotionality, but not control measures, on the assumption that a single underlying trait should influence performance on multiple measures of emotionality to a comparable degree and should not influence performance on control measures.

The results of a recent attempt to do this are presented in Figure 1. Figure 1a identifies QTLs that influence control measures (i.e., potential confounds unrelated to emotionality), and Figures 1b–c identify QTLs that influence one or more of five tests of facets of emotionality related to emotionality (elevated plus-maze, square maze, open field arena, light–dark box, and mirror chamber).

Comparisons between Rodents and Humans

Recently, evidence for an overlap between the genetic basis for emotionality in rodent models and trait neuroticism in humans has emerged. Although a number of studies in humans have investigated individual genes, direct comparability with animal models is better achieved by a linkage analysis of human sibling pairs in which evidence of deviation from the expected value of allele sharing at a given point along the genome is evidence for the presence of a QTL at that locus. In this way, we can ask whether individuals who are behaviorally similar (i.e., have similar trait neuroticism scores) are also genetically similar (i.e., share two alleles). One locus on chromosome 1, identified in humans as potentially related to trait neuroticism, is potentially promising because it may be syntenic with loci identified in animal studies. The congruence of genetic mapping in human and

animal studies may help determine whether there is a common set of genes that contribute to trait neuroticism in humans and analog models of emotionality in animals.

Conclusion

Introduction

Shiftwork may not be the typical stressor in the classic sense, but it affects the systems of stress and restitution in a very pronounced way and causes cardiovascular disease, gastrointestinal disease, and insomnia, among other conditions. Here we review some of the connections. But before that we need to look at the phenomenon of shiftwork. This is an arrangement of work hours through which the daily duration of production/service extends to cover operation during 2–3 work days compressed into one 24-h period. Each day is called a shift. Normally, the first step of extension beyond a day shift is to introduce morning and evening shifts (6 a.m.–2 p.m. and 2 p.m.–10 p.m., respectively). When necessary, a night shift may also be used to cover the remaining 8 h. In Europe, workers often alternate among shifts, working the same shift two to four times in succession and then switch-

ing to a new shift. In transport, health care and the service sector, the shifts may be more variable in placement and duration, but the principle of alternating among different shifts remains. Even the permanent night worker alternates between a night shift and day life during his days off. Usually, the night shift is the most problematic, causing disturbed circadian rhythms, disturbed sleep, and excessive sleepiness and several diseases deriving from these disturbances.

The Mechanism

Shift work would not present a problem were it not for the biological clock that drives physiology and psychology through a 24-h cycle, with high and low periods of activity. The central oscillator is situated in the hypothalamus. It is a self-sustained oscillator and drives much of our physiology in an approximately 24-h cycle. It receives input from light and other stimuli that synchronize the pacemaker with the environmental light–dark cycle, called Zeitgebers, which entrain (influence) the biological clock to the light–dark changes of the normal environment. Essentially, light before the circadian trough (low) phase delays the biological clock (1–2 h) and light after the trough phase advances the clock.

The influence of the circadian cycle on sleep was demonstrated in monthlong isolation studies in which individuals could live according to their own preferred sleep–wake schedules. This led to the finding that some individuals developed a period of around 25 h, and that some individuals desynchronized, showing different period lengths for their sleep–wake rhythm and for their rhythm of metabolism (rectal temperature). However, the present estimate of the period length with control for light is 24.1 h. It was later shown that whenever the sleep–wake

rhythm placed sleep around the acrophase (circadian maximum) of rectal temperature, sleep was shortened, and when sleep was placed around the circadian trough phase, sleep was promoted. Thus, the biological clock interfered with sleep and wakefulness.

Effects on Sleep

The dominant health problem reported by shiftworkers is disturbed sleep and wakefulness. At least three-quarters of the shift-working population is affected. When comparing individuals with a very negative attitude to shiftwork with those with a very positive one, the strongest discriminator seems to be the ability to obtain sufficient quality of sleep during the daytime. Electroencephalograph (EEG) studies of rotating shiftworkers and similar groups showed that day sleep is 1–4 h shorter than night sleep. The shortening is due to the fact that sleep is terminated after only 4–6 h without the individual being able to return to sleep. The sleep loss is primarily taken out of stage 2 sleep (basic sleep) and stage rapid-eye movement (REM) sleep (dream sleep). Stages 3 and 4 (deep sleep) do not seem to be affected. Furthermore, the time taken to fall asleep (sleep latency) is usually shorter. Night sleep before a morning shift is also reduced, but the termination is through artificial means and the awakening is usually difficult and unpleasant. Interestingly, day sleep does not seem to improve much across series of night shifts. It appears, however, that night workers sleep slightly better (longer) than rotating workers on the night shift.

As indicated previously, shiftwork sleep duration is approximately 5.5–6 h after the night shift, and several laboratory studies have found that this amount of sleep curtailment may affect sleepiness moderately. The 2003 study by Van Dongen and colleagues indicates that the critical point for the accumulation of fatigue is approximately 7 h of sleep per night. The circadian trough and extended wakefulness (often up to 20 h) are other powerful contributors.

Alertness

Night-oriented shiftworkers complain as much about fatigue and sleepiness as they do about disturbed sleep. The sleepiness is particularly severe on the night shift, appears hardly at all on the afternoon shift, and is intermediate on the morning shift. The maximum is reached toward the early morning (5 a.m.–7 a.m.). Frequently, incidents of falling asleep occur during the night shift. At least two-thirds of the respondents report that they have experienced involuntary sleep during night work. Ambulatory EEG recordings verify that incidents of actual sleep occur during

night work in, for example, process operators. Other groups, such as train drivers or truck drivers, show clear signs of falling asleep while driving at night. This occurs toward the second half of the night and appears as repeated bursts of alpha and theta EEG activity, together with closed eyes and slow undulating eye movements. As a rule, the bursts are short (1–15 s) but frequent and seem to reflect let-downs in the effort to fend off sleep. Approximately one-quarter of the subjects recorded show the EEG/electrooculograph (EOG) patterns of fighting with sleep. This is clearly a larger proportion than is found in the subjective reports of episodes of falling asleep.

Performance

As may be expected, sleepiness on the night shift is reflected in performance. One of the classic studies in this area is by Bjerner and colleagues, who showed that errors in meter readings over a period of 20 years in a gas works had a pronounced peak on the night shift. There was also a secondary peak during the afternoon. Similar observations have been made for switchboard operators and other groups. Late-night shift performance capacity has been compared with performance following the ingestion of alcohol to a 0.08% blood alcohol level.

Accidents

If sleepiness is severe enough, interaction with the environment ceases, and if this coincides with a critical need for action, an accident may ensue. Most of the available accident data on night-shift sleepiness has been obtained from the area of transportation; the National Transportation Safety Board ranks fatigue as one of the major causes of heavy vehicle accidents.

Very little relevant data are available from conventional industrial operations, but fatal work accidents show a higher risk in shiftworkers and accidents in the automotive industry may exhibit night-shift effects. An interesting analysis has been put forward by the Association of Professional Sleep Societies Committee on Catastrophes, Sleep and Public Policy. Its consensus report notes that the nuclear plant meltdown at Chernobyl occurred at 1:35 a.m. and was due to human error (apparently related to work scheduling). Similarly, the Three Mile Island reactor accident occurred between 4 and 6 a.m. and was due not only to the stuck valve, which caused a loss of coolant water, but also, more important, to the workers' failure to recognize this event, which led to the near meltdown of the reactor. Similar incidents (although with the ultimate stage having been pre-

vented) occurred in 1985 at the David Beese reactor in Ohio and at the Rancho Seco reactor in California. Finally, the committee also stated that the NASA Challenger space shuttle disaster stemmed from errors in judgment made in the early morning hours by people who had had insufficient sleep (because of partial night work) for days prior to the launch. Still, there is very limited support for the notion that shiftwork outside the area of transportation actually carries a higher over all accident risk.

As with sleep, the two main factors behind sleepiness and performance impairment are circadian cycle homeostatic factors. Alertness falls rapidly after awakening, but gradually levels out as wakefulness is extended. The circadian influence appears as a sine-shaped superimposition on this exponential fall in alertness. Akerstedt describes this as a three-process model of alertness regulation. Space does not permit a discussion of the derivation of these functions here.

Stress Indices

A number of studies have looked at the effect of shiftwork on endocrine and other stress-related parameters. The circadian pattern of cortisol, growth hormone, and melatonin is clearly affected by night work, but the adjustment to night work is only partial. We should also consider the increased cortisol levels and reduced insulin sensitivity following the reduction of sleep to 4 h. On the other hand, there do not seem to be any data on the long-term consequences of night work on stress indices, except perhaps for a suppression of testosterone in male nightworkers with a negative overall attitude to night shifts. Also, testosterone seems linearly related to sleep duration, as demonstrated in experimental studies of shifted sleep.

Gastrointestinal Effects

Gastrointestinal complaints are more common among night shiftworkers than among day workers. In a review of a number of reports covering 34 047 people with day or shiftwork, ulcers were found to occur in 0.3–0.7% of day workers, 5% of morning and afternoon shiftworkers, 2.5–15% of rotating shiftworkers with night shifts, and 10–30% of ex-shiftworkers. Several other studies have come to similar conclusions. Other gastrointestinal disorders, including gastritis, duodenitis, and dysfunctions of digestion are more common in shiftworkers than in day workers.

The pathophysiological mechanism underlying gastrointestinal diseases in shiftworkers is unclear, but one possible explanation is that intestinal enzymes

and intestinal mobility are not synchronized with the sleep–wake pattern. Intestinal enzymes are secreted with circadian rhythmicity, and shiftworkers' intake of food is irregular compared with intestinal function. A high nightly intake of food may be related to increased lipid levels, and eating at the circadian low point may be associated with altered metabolic responses. In addition, reduced sleep affects lipid and glucose metabolism. Recently, an epidemiological study showed a large increase in ulcer risk in shiftworkers with complaints of sleep or excessive sleepiness.

Cardiovascular Effects

A number of studies have reported a higher incidence of cardiovascular disease, especially coronary heart disease, in shiftworkers than in those who work days. In a study of 504 paper-mill workers followed for 15 years a dose–response relationship was found between number of years of shiftwork and incidence of coronary heart disease in the exposure interval 1–20 years of shiftwork. A study of 79 000 female nurses in the United States gave similar results, as did studies of more than 1 million Danish men and of a cohort of Finnish workers. Again, disturbances of metabolic parameters such as lipids and glucose might contribute to this. The effects of shiftwork on metabolic changes do not seem as pronounced, however, as those of stress. Very few studies are available, but the prevalence of endocrine and metabolic diseases seems increased in shiftworkers, including increased insulin resistance.

Mortality

The mortality of shift- and day workers was studied by Taylor and Pocock, who studied 8603 male manual worker in England and Wales between 1956 and 1968. Day, shift-, and ex-shiftworkers were compared with national figures. The standardized mortality rate (SMR) can be calculated from observed and expected deaths reported in the paper. SMRs for deaths from all causes were 97, 101, and 119 for day, shift-, and ex-shiftworkers, respectively. Although the figures might indicate an increasing trend, the differences were not statistically significant. However, the reported SMR close to 100 is remarkable because the reference population was the general male population. Most mortality studies concerned with occupational cohorts reveal SMRs lower than 100, implying a healthy worker's effect. The same study showed a significantly increased incidence of neoplastic disease in shiftworkers (SMR 116).

Conclusion

Shiftwork (with night shifts) impairs sleep and alertness and increases the risk of cardiovascular and gastrointestinal disease. It also disturbs the circadian timing of the endocrine and other systems. Thus, it may serve as one form of stressor and may combine with traditional psychosocial stressors.

Phenomenology of Frightening Awakenings
Nightmares and Posttraumatic Stress Disorder
Treatment Approaches

Glossary

Hypnagogic and hypnopompic hallucinations Vivid sensory images occurring at the transition between sleep and wakefulness. Hypnagogic refers to hallucinations occurring as a person falls asleep

while hypnopompic images occur as a person awakens. Hypnagogic imagery may be particularly vivid during rapid eye movement (REM) sleep occurring at sleep onset (as in narcolepsy). Similarly, dreamlike hypnopompic images may continue during wakefulness upon sudden or partial awakening from REM sleep. Hypnagogic and hypnopompic hallucinations may be accompanied by a complete inability to move (sleep paralysis).

Nachtmare

Nacht (night) + mare (spirit or monster). Mythologies throughout the world describe devils, demons, evil spirits, ogres, ghosts, vampires, old hags, and witches that attack individuals while they sleep. The *mare* usually sits on or crushes the sleeper's chest causing a smothering sensation and an inability to breathe. Additionally, the individual is usually unable

	to move. Sometimes there are sexual overtones as well with the spirit raping or assaulting the person while they lay paralyzed. This description suggests the occurrence of the parasomnia sleep paralysis accompanied by a hypnagogic or hypnopompic hallucination.
<i>Night terror (also known as sleep terror)</i>	A sleep disorder usually arising from slow-wave sleep that involves a sudden awakening with intense fear. The afflicted individual usually emits a sharp piercing scream. Autonomic nervous system activation accompanies the awakening and the individual will often have tachycardia, tachypnea, sweating, and increased muscle tone. The individual typically acts confused, disoriented, and inconsolable during the episode; however, there may be complete amnesia about the episode upon awakening the next morning.
<i>Parasomnia</i>	A disorder of arousal, partial arousal, or sleep stage transition. Parasomnias occur episodically during sleep and may interfere with sleep, sometimes producing insomnia or daytime sleepiness.
<i>Rapid eye movement (REM) sleep</i>	REM sleep is one of the five sleep stages defined in humans. REM sleep was discovered by Eugene Aserinsky who noted eye movements occurring every 90–100 minutes during sleep. In initial studies, dream recall was better correlated with awakenings from REM than other sleep stages. Consequently, REM sleep came to be considered the biological substrate of dreams.
<i>Sleep paralysis</i>	The inability to perform voluntary movements upon awakening from sleep or just before sleep onset. The individual is fully conscious, usually feels acutely anxious, typically is unable to vocalize, and may have hallucinatory activity accompanying the paralysis episode.

Nightmares, according to current terminology, are unpleasant, distressing, or frightening dreams that usually occur during rapid eye movement (REM) sleep. The International Classification of Sleep Disorders—Second Edition (ICSD-2) formally classifies the nightmare disorder as a parasomnia usually associated with REM sleep. Nightmares, as currently defined are “coherent dream sequences that seem real and become increasingly more disturbing as they unfold. Emotions usually involve anxiety, fear, or terror but frequently also anger, rage, embarrassment, disgust, and other negative feelings. Dream content most often focuses on imminent physical

danger to the individual but can also involve distressing themes.” The fears produced by the dream usually dissipate rapidly after awakening and clear sensorium returns.

Phenomenology of Frightening Awakenings

Although nightmares are currently conceptualized as frightening dreams that usually produce an awakening from REM sleep, the term derives from *nachtmare* which refers to a quite different phenomenon. The *nachtmare* (or night spirit) has taken many forms in folk lore and superstition, ranging from vampires (in Medieval Eastern Europe) to witch riders (among preAmerican Civil War slaves). Contemporary alien attacks are likely an offshoot of the same disorder. The *nachtmare* accompanies sleep paralysis with frightening hypnagogic or hypnopompic hallucinations and characteristically arise during the transition from wakefulness to sleep. The sleeper has difficulty breathing due to the creature sitting on his or her chest, there may also be a sense of sexual molestation, the sleeper may feel that their life force is being sucked out of them. To complicate things further, the mythical *nachtmares* Incubus and Succubus are commonly associated with yet as distinctly different phenomenon: the sleep terrors (*Pavor nocturnus*). Sleep terrors usually occur in slow-wave sleep, are not dreamlike, and are poorly recalled. The person may remember a frightening image; however, narrative and plot are rare.

By contrast, the nightmare in modern parlance explicitly arises from a dream, implying imagery, narrative, and plot. Individuals awakened from a dream typically recollect its content. Nightmares may afflict 10–50% of children and 50–85% of adults have at least an occasional nightmare. Overall estimates for the prevalence of nightmares range from 2–8% in the general population. Nightmares arising from either acute or posttraumatic stress disorders (PTSDs) may occur in stage 2 sleep as well as during REM sleep. However, there are other widely recognized types of awakenings associated with subjective reports of panic, dysphoria, or anxiety. These included sleep-related panic attacks, sleep terrors, and sleep paralysis with hypnagogic or hypnopompic hallucinations. These paroxysmal events arise from different stages of sleep. Like REM sleep nightmares, sleep-related panic attacks are characterized by awakening with fear. Polysomnography reveals that these episodes customarily occur during sleep stage 2, often during transition to slow-wave sleep. However, sleep-related panic attacks may occur, although rarely, at the wake-to-sleep transition.

Nightmares and Posttraumatic Stress Disorder

Nightmare frequency increases during periods of stress and after an individual experiences a distressing event (e.g., an automobile accident, burglary, rape, or death of a friend or relative). Stress and sleep deprivation are also thought to exacerbate sleep paralysis, sleep terrors, and sleep-related panic attacks. One approach to exploring the relationship between stress and these phenomena is to study the sleep in individuals with PTSD.

Silva and colleagues reported on symptoms in 131 physically or sexually abused women interviewed in a primary care setting. They found that 65% reported bad dreams, flashbacks, and/or terror attacks. These women had higher intrusion and avoidance scores. Nightmares are also reported in school age children after being involved as passengers in traffic accidents. Psychological consequences were common and persisted in 33% of children after 4–7 months. Eleven percent were thought to be severely afflicted on follow up with 17% reporting nightmares and other sleep difficulties. Nightmares related to trauma are known to persist for prolonged periods. A study of Dutch war veterans found nightmares and anxiety dreams 40 years after the traumatizing event. In a large survey of Vietnam War veterans, using a careful sampling technique, nightmare frequency strongly correlated with combat exposure. Insomnia also was associated with combat exposure but not to the same degree as nightmares. By contrast, neither chronic medical illnesses nor psychiatric disorders (panic disorder, major depression, mania, and alcohol abuse) could predict nightmare frequency.

Although recurrent distressing dreams are a key PTSD diagnostic feature according to DSM-IV, the nature of these nightmares is in question. Many clinicians assume that PTSD nightmares represent a REM sleep phenomenon; however, PTSD nightmares are poorly understood. In many respects their features conform to those present in REM sleep nightmares. They typically contain imagery, narrative, and plot. However, the repetitive, recurring nature of these nocturnal frightening phantasms makes them unusual. Another uncommon characteristic of chronic PTSD nightmares is that they narrate traumatic events, often without elaboration or symbolism. Several published descriptions of PTSD nightmares include the adrenergic concomitants tachycardia and sweating that are atypical of REM sleep. These features more commonly accompany sleep terrors. Thus, it is not surprising that some sleep experts contend that PTSD nightmares can arise from any stage of sleep. Hartmann in his extensive monograph on

nightmares flatly states that PTSD nightmares "... are not typical REM nightmares; they occur sometimes in stage 2 and sometimes in all stages of sleep and even at sleep onset..." Kramer and Kinney also emphasize that PTSD nightmares can arise from both REM and stage 2 sleep.

Ross and associates argue strongly that REM sleep disturbance is closely involved in the pathogenesis of PTSD. This disturbance may be either "inappropriate recruitment of essentially normal REM sleep processes" or involvement of "inherently dysfunctional REM sleep mechanisms". They correctly contend that the vividness and recallability of PTSD nightmare content has more in common with REM than non-REM mentation. REM sleep is comprised of an array of individual features, including: low amplitude, mixed frequency electroencephalograph (EEG) activity; rapid eye movements; muscle atonia; pontine geniculate occipital (PGO) discharges; small muscle twitches; periorbital integrated potentials (PIPs); and middle ear muscle activity (MEMA). Although these activities usually occur in concert, they sometimes dissociate, as in REM sleep behavior disorder (RBD). In RBD, the atonia that characteristically accompanies REM sleep is absent. In fact, Ross and colleagues suggest RBD as a possible model for the pathophysiological mechanism underlying PTSD nightmares. In their overnight polysomnographic studies, these researchers showed that combat veterans with PTSD had elevated REM sleep percentage, longer average REM cycle duration, and increased REM density (number of eye movements per minute of REM sleep) compared to controls. These same investigators also report more phasic leg muscle activity during REM sleep in veterans with PTSD than in those without PTSD. Admittedly, the sample was small; however, these studies provide a foundation for further research.

Neuropharmacology of REM sleep clearly demonstrates involvement of cholinergic mechanisms. It is also widely accepted that acetylcholine plays an important role in the formation of memories. It has also been postulated that REM sleep mediates memory consolidation. When high adrenergic arousal accompanies a remembered experience (as occurs with acute trauma or re-experiencing a distant trauma), it appears that the memory process functions differently. Memories can be triggered by adrenergic arousal. The relationship between this arousal, flashbacks, and nightmares underlie current neuropsychiatric conceptualization of the consequences of traumatic stress. REM sleep has been characterized as a parasympathetic state with bursts of sympathetic activity (associated with phasic events). Nightmares and

recurrent dreams may be considered a failure of dreamwork to handle emotionally laden, presumably adrenergically coupled experiences.

PTSD nightmares are reported in 92% of patients with flashbacks and 57% of patients without flashbacks, they seldom occur during laboratory sleep studies. This is the case even among patients who indicate having nightmares four or more times per week. Nonetheless, on several occasions during our 30 years of clinical polysomnography experience, patients had nightmares while sleeping in the laboratory. On those rare occasions, we noticed increased REM density just before awakenings associated with nightmares. Consultation with several sleep disorder medicine colleagues revealed that this is a widely held impression (e.g., Drs. Hartmann (Boston, MA), Roffwarg (Jackson, MS), Mendelson (Chicago, IL), and Mahowald (Minneapolis, MN)). To the best of our collective knowledge and according to thorough search using medical databases, little systematic data exists beyond description of the phenomenon. Ross and associates mention exceedingly high REM density preceding a nightmare that fortuitously occurred during their study. We also have observed vastly increased phasic activity in combat veterans with PTSD referred to our Sleep Diagnostic Clinic for evaluation of insomnia, nightmares, or daytime sleepiness.

A phasic activity threshold likely exists that is necessary but not sufficient to produce nightmares. The level of phasic activity is elevated in patients with PTSD compared to control subjects. This conceptualization is analogous to the relationship between hypersynchronous slow-wave activity and parasomnias of arousal (confused awakening, sleepwalking, and sleep terror). Another perspective is suggested by the well-established relationship between sleep and some forms of epilepsy. Abnormal spike activity is enhanced by sleep deprivation. Interestingly, some neurophysiologically oriented researchers have posited a kindling model for flashbacks and nightmares. More research is needed to illuminate the biological substrate underlying the dysphoric mentation and paroxysmal awakenings that we call nightmares.

Treatment Approaches

Nightmares are experienced acutely (at some period during the lifetime) in many individuals. Furthermore, they typically resolve without intervention. However, persistent nightmares, particularly if the dream content is recurrent, can be a marker for significant psychopathology. In such cases, treatment is advised especially when the nightmare produces serious distress, insomnia, or interferes with daily

activities. Similarly, nightmares in early childhood (preschool and early school years) are of less concern (assuming they are outgrown) than those beginning or persisting in late childhood and adolescence. In adults, the frequency of psychopathology is higher among patients suffering from chronic nightmares than in control subjects. Hartmann posits that nightmare sufferers have thin boundaries, are more vulnerable, and have weaker psychological defenses. He also suggests that these individuals are at risk for schizophrenia. In addition to this profile for patients with nightmares, traumatic events apparently can induce nightmares. The nightmares may be immediate or delayed. They may afflict the individual acutely or persist for many years. Finally, drug abuse, drug or alcohol withdrawal, and specific medications are associated with nightmares. Thus, treatment must start with a careful history emphasizing current stressors, possible traumatic experiences, psychopathology (in patient and family), alcohol and drug abuse, and medication regimen.

Several medications have been associated with increased chance of nightmares. Some of them act by potentiating REM sleep and others by producing REM sleep rebound on withdrawal. Such drugs include L-DOPA, reserpine, thiothixene, alpha methyl dopa, metoprolol, propranolol, simvastatin, and atorvastatin. Interestingly, in addition to several statins appearing to induce nightmares, there is also a report by Ararun and associates (2005: 361–364) that nightmares are associated with low serum lipid levels.

Altering dose or substituting other pharmacological agents would be the first step in such cases. Alcohol or stimulant withdrawal also potentiates nightmares via presumed REM sleep mechanisms. In such cases, nightmares should be time-limited and resolve when sleep normalizes. If nightmares persist, intervention should be considered.

When psychopathology is found, it should be treated directly. Psychotherapy is thought to be beneficial. It is worth emphasizing that insomnia resulting from fear of sleep can pose a serious treatment obstacle. Sleep deprivation exacerbates nightmares, sleep terrors, and sleep paralysis attacks. Thus, the nightmare may perpetuate insomnia and thereby produce a vicious cycle. Behavioral interventions for insomnia are safe and effective in both the short and long term. Improved sleep hygiene, stimulus control therapy, sleep restriction therapy, and/or cognitive therapy are recommended. Krakow and Zadra (2006: 45–70) directly target the nightmare with imagery rehearsal therapy (IRT) with good results using four, 2-hour sessions. Another reportedly successful behavioral approach is lucid dream therapy. A lucid dream is one in which the dreamer becomes aware that he or

she is dreaming. In an uncontrolled case series of five individuals that could be trained to recognize their dream state, nightmare frequency declined. Whether the decline related to increased lucidity or volitional alteration of dream content is unknown. In some cases, medications may be needed. Several medications reportedly provide some relief from nightmares when administered to patients with PTSD. Davidson and colleagues report decreased nightmare and general sleep disturbance scores in response to the atypical antidepressant nefazodone in a group of 17 patients treated with up to 600 mg day⁻¹ for 12 weeks. Other antidepressants have been tried. Cavaljuga and co-workers (2003: 12–16) found fluoxetine more effective at reducing nightmares than amitriptyline; however, amitriptyline was more effective overall in acute PTSD. In another study by Gupta and co-workers, cyproheptadine (4–12 mg at bedtime) was found to be beneficial on retrospective review of nine patient charts. Response to this histamine-1 blocking, serotonin antagonist ranged from decreases in nightmare frequency (or intensity) to complete remission.

At present, the most systematic work on pharmacological treatment of nightmares is with prazosin. Peskind and colleagues (2003: 165–171) treated nine older men with posttraumatic nightmares with 2–4 mg prazosin 1 hour before bedtime. The drug substantially reduced nightmares in eight of the patients and was well tolerated. Furthermore, a 20-week, double-blind, crossover trial was conducted by Raskind and associates (2003: 371–373) in 10 Vietnam theatre combat veterans. A mean dose of 9.5 mg of prazosin was given at bedtime. Drug, compared to placebo, significantly reduced scores on recurrent distressing dreams.

In a review article concerning nightmare treatments, van Liempt (2006: 193–202) concludes that open-label reports suggest efficacy for some antidepressants, anticonvulsants, and atypical antipsychotic drugs. Placebo-controlled studies show possible efficacy with olanzapine and prazosin. We find these preliminary results are encouraging; however, more double-blind, placebo-controlled trials are needed. Finally, assorted benzodiazepines can provide relief from dream anxiety and help improve sleep. However, few randomized, placebo-controlled, clinical trials have been conducted and they had small sample sizes. Furthermore, the withdrawal effects from pharmacotherapeutic interventions have not been systematically studied.

Glossary

Adrenocorticotrophic hormone (ACTH) A polypeptide hormone secreted from the corticotropes of the anterior pituitary that stimulates the secretion of glucocorticoids (cortisol in human, corticosterone in rat) from the adrenal cortex.

Cytokine A polypeptide or small protein secreted classically by cells of the immune system, such as lymphocytes, monocytes, and macrophages, and now known to be secreted by other cells, such as endothelial cells and adipocytes. In many instances, cytokines have autocrine, paracrine, and endocrine effects to alter growth and function of their target cells.

Follicle-stimulating hormone (FSH) A heterodimeric glycoprotein secreted by gonadotropes of the anterior pituitary that promotes follicular growth in the ovaries and spermatogenesis in the testes and interacts with the luteinizing hormone to produce estrogen secretion by the ovarian follicles.

Growth hormone (GH) A protein hormone secreted by the somatotropes of the anterior pituitary that is responsible for growth by anabolic

Interferon γ

Interleukin (IL)

Luteinizing hormone (LH)

Prolactin (PRL)

Thymosin α_1

Thyroid-stimulating hormone (TSH)

effects in many tissues often mediated by insulin-like growth factor I, secreted principally by the liver.

One of several interferons that particularly has antiviral activity in contrast to the antibacterial activity of many of the interleukins.

A group of cytokines. IL-1 is a pro-inflammatory cytokine and was the first cytokine to be characterized; two closely related proteins, IL-1 α and β , have similar actions on closely related receptors in many tissues. Subsequently characterized cytokines were named in the order of their discovery. IL-2 is a pro-inflammatory cytokine. IL-10, IL-13, and IL-1 receptor antagonist are anti-inflammatory cytokines.

A heterodimeric glycoprotein secreted by gonadotropes of the anterior pituitary that induces ovulation and corpus luteum formation, estradiol secretion from the follicle, and progesterone secretion from the corpus luteum of female mammals and stimulates the interstitial tissue of the testis to secrete testosterone in males.

A protein hormone, related to growth hormone, secreted by the lactotropes of the anterior pituitary. Its best known function is to stimulate the growth and secretion of milk from the mammary gland. In males, it affects male sex accessories. It also has actions on the cells of the immune system that enhance immune responses.

A polypeptide cytokine secreted by the thymus that has paracrine and hormonal actions.

A heterodimeric glycoprotein secreted by the thyrotrope of the anterior pituitary that stimulates the secretion of thyroid hormones.

Tumor necrosis factor α A pro-inflammatory cytokine mediating local inflammatory and systemic responses to infection. It was named according to its originally described action; also known as cachectin.

Stress may be defined as any stimulus that distorts homeostasis in the organism. Therefore, stress can be physical, as in the case of excessive heat or cold, trauma, surgical operations, or infection, or it can be emotional and psychological. Selye, who coined the term, even talked about the stress of life itself. It is the stresses of life that contribute to degenerative disease and old age.

Stress can affect every organ system in the body, but the principal mediators of the response to stress are the sympathetic nervous system and the hypothalamic-pituitary-adrenal axis. Various hypothalamic-releasing and -inhibiting hormones are released from their axon terminals in the median eminence (ME) into the capillaries of the hypophyseal portal veins that transport them to the anterior lobe of the pituitary gland. There they stimulate or inhibit the release of the various pituitary hormones that act either directly on body tissues or on their target glands, which in turn release hormones that act on various tissues of the body. Examples of the latter are adrenocorticotrophic hormone (ACTH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH); examples of the former are prolactin (PRL) and growth hormone (GH).

In the dozen years since the discovery of nitric oxide (NO) in the body and the enzymes forming it, it has become evident that NO plays a pivotal role in the function of every organ system of the body. This article first examines the role of NO under physiological conditions and then indicates how this role is affected by stress. In this connection, most attention has focused on the role of NO in the induction of the responses to infection. Little attention has been given so far to its role in psychological and other types of stress.

Role of Nitric Oxide in Physiological Release of Hypothalamic Neuropeptides and Transmitters

Corticotropin Releasing Hormone

The release of corticotropin releasing hormone (CRH) from hypothalami incubated *in vitro* is controlled by muscarinic cholinergic receptors because it can be blocked by atropine. The acetylcholine-producing interneurons in the hypothalamus release

acetylcholine, which stimulates a muscarinic-type receptor, which in turn stimulates CRH release from the CRH neurons. Neural NO synthase (nNOS) has been located in neurons in the paraventricular nucleus (PVN) of the hypothalamus. Stimulated CRH release can be blocked by N^G-monomethyl-L-arginine (NMMA), a competitive inhibitor of all forms of NOS. Consequently, CRH release from the neurons in the PVN is stimulated by cholinergic neurons that synapse on these NOergic neurons to activate NOS. NOS synthesizes NO, which diffuses into the CRH neurons and activates CRH release by activating cyclooxygenase I (COX I), leading to the generation of prostaglandin E₂ (PGE₂) from arachidonate (AA). PGE₂ activates CRH via the activation of adenyl cyclase and the generation of cyclic adenosine monophosphate (cAMP). cAMP activates protein kinase A, which induces the exocytosis of CRH secretory granules into the hypophyseal portal vessels that then activate ACTH release from the corticotrophs of the anterior pituitary gland. NO activates not only COX, but also lipoxygenase (LOX), which also plays a role in the activation of CRH release. NO also activates guanylyl cyclase (GC), which converts guanosine triphosphate into cyclic guanosine monophosphate (cGMP). cGMP is postulated to increase intracellular [Ca²⁺], which is required to activate phospholipase A₂, which converts membrane phospholipids into AA, the substrate for COX and LOX, permitting the generation of prostaglandins (PGs) and leukotrienes, respectively. The activation of CRH release can be blocked by the synthetic glucocorticoid dexamethasone and also by blockers of the three pathways of AA metabolism (e.g., clotrimazol, which blocks epoxygenase, which converts AA into epoxides, and indomethacin, which inhibits COX) and by 5' 8' 11-eicisotrienoic acid, which blocks LOX. Thus, CRH release is activated by the AA cascade. α -Melanotropic-stimulating hormone (α -MSH) also inhibits CRH release. Cyclosporin inhibits CRH release as well, probably by inhibiting calcineurin. Calcineurin dephosphorylates NOS, rendering it active.

Luteinizing Hormone-Releasing Hormone

The role of NO in luteinizing hormone-releasing hormone (LHRH) release has been elucidated. Norepinephrine (NE), glutamic acid (GA), and oxytocin stimulate LHRH release by activation of nNOS. The pathway is as follows. Oxytocin and/or GA activate NE neurons in the medial basal hypothalamus (MBH), which activate NOergic neurons by α_1 -adrenergic receptors. The NO released diffuses into LHRH terminals and induces LHRH release by the activation of GC and COX. NO controls not only the release of

LHRH bound for the pituitary, but also that which induces mating activity by actions in the brain stem. The adipocyte hormone, leptin, also increases the release of LHRH from medial basal hypothalamic explants by stimulating the release of NO. However, β -endorphin and γ -aminobutyric acid (GABA) block the activation of LHRH release by NO. In contrast to the clear evidence for the stimulation of LHRH release by NO, it apparently has no effect on FSH release mediated by the FSH releasing factor.

Other Hypothalamic Peptides

Evidence from *in vivo* experiments suggests that NO also stimulates the release of GH releasing hormone (GHRH), and *in vitro* experiments clearly show that it also stimulates the release and synthesis of somatostatin. The release of oxytocin and vasopressin from the hypothalamus is suppressed by NO. NO stimulates the release of the PRL-inhibiting hormone, dopamine.

Effects of Nitric Oxide on the Release of Pituitary Hormones

nNOS is present in folliculostellate (FS) cells, a cell type of the anterior pituitary not previously thought to produce hormones but that is now known to produce several cytokines. nNOS has also been found in LH gonadotrophs. NO produced by this nNOS in the pituitary has important functions in altering pituitary hormone secretion. Intravenous injection of nitro-arginine methyl ester (NAME) augments vasopressin-induced ACTH release, so NO probably blocks ACTH secretion induced by vasopressin or CRH, but this has not been studied directly. NO inhibits PRL secretion. Apparently, NO from FS cells diffuses to adjacent lactotrophs where it induces the production of cGMP by activating GC. cGMP then inhibits PRL release by blocking the exocytosis of PRL secretory granules.

The principal PRL-inhibiting hormone, dopamine, apparently acts on cell surface D2 receptors on FS cells to activate NOS followed by NO production. However, the action of FSH-releasing factor (FSHRF), LHRH, and leptin to stimulate not only FSH but also LH is brought about by their action on specific receptors on gonadotrophs to activate nNOS, thereby generating cGMP, which, instead of inhibiting, as in the case of lactotropes, promotes hormone secretion. Specificity of action of these compounds on gonadotropin release is accomplished by specific receptors for each of these ligands that increase intracellular $[Ca^{2+}]$, thereby activating nNOS. Both LHRH and leptin preferentially stimulate LH with a lesser potency to release FSH, whereas FSHRF selectively releases FSH and has a lower potency to release

LH. In this way, it is possible to have differential effects of various stimuli on FSH and LH secretion. This mechanism accounts for the pulses of FSH alone generated by FSHRF and of LH alone generated by LHRH.

Role of Nitric Oxide in Stress-Induced Alterations in Hypothalamic-Pituitary Function

Nearly all types of stress elicit a stereotyped pattern of pituitary hormone secretion in humans that consists of a rapid increase in ACTH, PRL, and GH secretion (in rats, GH secretion is inhibited) and inhibition of the secretion of LH, TSH, and, to a lesser extent, FSH. The pattern is caused primarily by alterations in the secretion of hypothalamic-releasing and -inhibiting hormones.

Immediate Response to Infection

The role of NO has been studied extensively in a model of the stress from infections that consists of injecting bacterial lipopolysaccharide (LPS) intravenously (IV) or intraperitoneally (IP). This induces an identical pattern of pituitary hormone secretion as that seen in infection. There is a very rapid increase in plasma ACTH and PRL within a few minutes following the IV injection of LPS. The response is dose-related and is accompanied by a rapid inhibition of LH and TSH (but not FSH) secretion. GH secretion is stimulated in humans but suppressed in rats. This initial response to LPS is mediated by the constitutive nNOS present in the brain. There is no participation of the NO synthesized by inducible NOS (iNOS) in this initial response. Indeed, the initial response must be due to action on receptors for LPS on the endings of vagal afferents and also in areas where the blood-brain barrier is not present, such as the choroid plexus, ME, organum vasculosum lamina terminalis (OVLT), area postrema, and other circumventricular organs. LPS alters the release of the various hypophysiotropic hormones, increasing the release of CRH and vasopressin, GHRH, and somatostatin, particularly in the rat, which overpowers the effect on the release of GHRH. LPS decreases the release of dopamine, the PRL-inhibiting hormone; LHRH; and TRH (but not FSHRF). All of these pathways involve the participation of nNOS as described earlier. Input to the hypothalamus from LPS by vagal afferents occurs, at least in part, by activation of the locus ceruleus, which sends noradrenergic axons to the hypothalamus to activate CRH release.

In the authors' studies, LPS itself had no acute effect on ACTH release from hemianterior pituitaries *in vitro*. However, LPS induces cytokine production

in the pituitary. Cytokine production would be increased in a few hours and undoubtedly would modify the responses of the pituitary to the continued altered secretion of releasing and inhibiting hormones.

Delayed Response

Central nervous system (CNS) infection is a powerful inducer of cytokine production in glia and neurons of the brain, which causes the induction of iNOS and the production of potentially toxic quantities of NO. Following IV injection of an intermediate dose of LPS, there was an induction of IL-1 α immunoreactive neurons in the preoptic-hypothalamic region. These cells were shown to be neurons by the fact that double staining revealed the presence of neuron-specific enolase. The neurons were found in saline-injected control animals, suggesting that they are normally present, but they increased in number by a factor of two within 2 h following injection of LPS. They are located in a region that also contains thermosensitive neurons. They may be the neurons that are stimulated to induce fever following the injection of LPS. They have short axons that did not project clearly to the areas containing the various hypothalamic-releasing and -inhibiting hormones, but they could also be involved in the stimulation or inhibition of their release, which occurs following infection.

This study led to further research that demonstrated that the IP injection of a moderate dose of LPS induced IL-1 β and iNOS mRNA in the brain, anterior pituitary, and pineal glands. The results were very exciting because an induction of IL-1 β and iNOS mRNA occurred with the same time course as found in the periphery following the injection of LPS, namely, clear induction of IL-1 β followed by iNOS mRNA within 2 h, reaching a peak in 4–6 h, followed by a decline to near basal levels at the next measurement by 24 h after the injection. The induction of both mRNAs occurred in the meninges; choroid plexus; circumventricular organs, such as the subfornical organ and ME; ependymal cells lining the ventricular system; and, very surprisingly, parvocellular neurons of the PVN and arcuate nucleus (AN), areas of particular interest because they contain hypothalamic-releasing and -inhibiting hormone-producing neurons and also other neurotransmitters controlled by NO. The greatest induction occurred in the anterior lobe of the pituitary, where the iNOS mRNA was increased at 2 h by a factor of 45 and in the pineal where the activity was increased at 6 h by a factor of 7, whereas the increase in the PVN was fivefold. At 6 h, the medial basal hypothalamus was found to have an increased content of NOS measured *in vitro* and the collected cerebrospinal fluid (CSF) had

increased concentrations of the NO metabolite nitrate. These results indicate that the increase in iNOS mRNA was followed by the *de novo* synthesis of iNOS that liberated NO into the tissue and also into the CSF. Presumably, LPS was bound to its receptors in the circumventricular organs and in the choroid plexus. These receptors, as in macrophages, activated DNA-directed IL-1 β mRNA synthesis, which, in turn, caused the synthesis of IL-1 β . IL-1 β then activated iNOS mRNA and synthesis.

How can neurons in the AN and PVN be activated inside the blood–brain barrier? In the case of the AN, the neurons may have axons that project to the ME. These neurons may have LPS receptors on their cell surface, which then induce IL- β mRNA and IL-1 β synthesis. IL-1 β then induces iNOS mRNA followed by NO synthesis. Alternatively, LPS, acting on its receptors, may induce IL- β mRNA and iNOS mRNA simultaneously.

Active transport mechanisms for IL-1 and other cytokines, and perhaps LPS, are present in the choroid plexus. On the basis of the authors' results, cells of the choroid plexus must have LPS receptors on them. LPS then stimulates IL-1 β and iNOS mRNA, followed by the synthesis of IL-1 β and iNOS in the choroid plexus. LPS and IL-1 β are then transported into the CSF. LPS is carried by CSF flow to the third ventricle, where it either crosses the ependyma or acts on terminals of PVN neurons in the ependyma to induce IL-1 β and iNOS mRNA. This massive delayed increased NO production should further increase the effects of NO to maintain the pattern of hypothalamic hormone secretion already induced by LPS. Unfortunately, the effect of inhibitors of NOS on these later stages in the response to LPS or infection has not yet been studied. Interestingly enough, in studies on LHRH release induced by NO, it has been shown that increasing concentrations of NO provided by the release from sodium nitroprusside (NP) produce a bell-shaped dose–response curve in terms of LHRH release, with values reaching a peak and then declining as the concentration of NO increases. Therefore, the massive increase in NO produced by iNOS, several hours after injection of LPS, might actually reduce the effects of NO on releasing hormone discharge below the peaks achieved earlier.

In addition to inducing the production of pro-inflammatory cytokines such as IL-1, IL-2, IL-6, and TNF- α , LPS also induces the production of anti-inflammatory cytokines such as IL-10 and L-13 and the IL-1 receptor antagonist in the brain, pituitary, and pineal gland. In the periphery, these inhibit the inflammatory response induced by the pro-inflammatory cytokines. Limited studies indicate

that these anti-inflammatory cytokines antagonize the actions of the pro-inflammatory cytokines in the brain as well as the hypothalamic-pituitary response to infection.

Direct Actions of Lipopolysaccharide, Cytokines, and Nitric Oxide on the Anterior Pituitary Gland during Infection

As indicated earlier, LPS had no acute direct effect to alter ACTH release from incubated pituitaries. Thus, the initial LPS-induced changes in pituitary hormone secretion are mediated by the altered release of hypothysiotropic hormones; however, LPS induces a massive induction of cytokine and, consequently, iNOS production in the anterior pituitary. Therefore, after the first few hours these cytokines and the massive release of NO will certainly modify the response of the gland to the hypothalamic factors. Unfortunately, these later times after LPS have not been studied experimentally.

Interleukin 1 The effects of IL-1 β and several other cytokines released by LPS have been studied extensively *in vitro*. It was reported that IL-1 releases ACTH and other pituitary hormones from perfused pieces of pituitary glands. In the case of the other cytokines, the authors have found actions on the pituitary gland; however, it required a period of 1–2 h for these actions to become manifest.

Tumor necrosis factor α After at least 1 h of incubation, TNF- α stimulated the release of ACTH, GH, TSH, and minimally PRL from either overnight-cultured dispersed pituitary cells or hemipituitaries; however, the minimal effective dose (MED) for these actions of TNF- α was 100-fold greater with dispersed cells than with hemipituitaries. We speculate that this decreased sensitivity in the dispersed cell preparation is due either to the loss of receptors or to paracrine actions of various pituitary cells to augment the effects on other pituitary cells in the hemipituitary preparation. There was a bell-shaped dose–response curve of response of the pituitaries, and the MED of 10^{-12} M for the hemipituitaries is within the concentrations that might be encountered *in vivo* in infection. Consequently, the authors concluded that cachectin may play an important role in altering pituitary hormone release by direct actions on the gland in infection; however, because of the relatively slow onset of these actions, it is likely that the acute response to infection is brought about by alterations in the release of hypothalamic-releasing and -inhibiting hormones, which then affect the gland. During more chronic infection, the actions at the pituitary

modulate the effects on the release of the hypothalamic peptides.

Interleukin 6 The incubation of IL-6 with hemipituitaries *in vitro* for at least 2 h increased the release of ACTH and GH only into the culture medium at the single concentration of 10^{-13} M. Concentrations of 10^{-14} or 10^{-12} M were ineffective. Again, there was a bell-shaped dose–response curve with the abolition of the actions with higher doses. Using 4-day monolayer-cultured cells, Spangelo and co-workers found not only an IL-6-induced increase in GH release but also an increase in PRL release. These differences may be accounted for by the different preparations of IL-6 used or, perhaps more likely, by their use of the dispersed cell system. This system may result in up- or downregulation of receptors for IL-6 in the relative absence of endogenous ligand and loss of paracrine actions because of separation of the cells. Because IL-6 is clearly produced by the pituitary gland itself and the production is increased by LPS (see earlier discussion), it is quite likely that IL-6 has important direct actions on the pituitary to modify pituitary hormone release. These actions probably modulate the effects of the cytokine on the release of hypothalamic hormones mentioned previously.

Therefore, the effect of IL-6 released from the hypothalamus and pituitary and also reaching the gland after release in the periphery during infection is the result of its actions at both the hypothalamic and pituitary levels, which induces a stimulation of ACTH and GH, and a decrease in TSH release in acute situations *in vivo*.

The authors have not investigated chronic exposure to IL-6. It is quite likely that there might be other effects, perhaps similar to those that occur in infection, with chronic exposure to this IL. Indeed, the acute effects of most of the cytokines at hypothalamic and pituitary sites can be characterized over a short period of an hour or two; however, much more research should be done to characterize the effects of more prolonged exposure of both the hypothalamus and the pituitary gland to these substances.

Interleukin 2 IL-2 is the most potent agent known to act directly on the pituitary to alter pituitary hormone release. At a concentration of 10^{-15} M, it elevated PRL and TSH release and inhibited the release of FSH, LH, and GH from hemipituitaries *in vitro*. ACTH release was induced with a higher concentration (10^{-12} – 10^{-10} M). After reaching the minimal effective stimulatory or inhibitory concentration, the dose–response curve was flat, but at much higher concentrations (10^{-9} or 10^{-8} M), responses tended

to diminish to insignificant values. Again, a bell-shaped dose–response curve was obtained similar to those observed with other cytokines.

Interferon- γ The incubation of INF- γ with hemipituitaries *in vitro* revealed no effect on the release of PRL, TSH, and GH, and it revealed a stimulation of ACTH release only at the relatively high concentration of 10^{-8} M. Later studies revealed that, at a concentration of 10^{-12} M, INF- γ also decreased the release of GH from pituitaries incubated *in vitro*. At a much higher concentration (10^{-8} M), it potentiated GH release induced by growth releasing hormone (GRH) but had no direct effect by itself. Because this is a 10,000-fold increase in dose over that which produced the inhibition of release, the authors question whether it is of pathophysiological significance. This inhibitory action on GH release vanished with higher doses, again giving the bell-shaped dose–response curve indicated earlier.

Thymosin α_1 Thymosin α_1 evoked a dose-dependent release of TSH and ACTH, although there was no effect on the release of PRL and GH from hemipituitaries incubated *in vitro*. There was a remarkable ability of the peptide to stimulate LH in a dose-related manner at a dose as low as 10^{-12} M, whereas FSH release was unaltered. Because thymosin α_1 has been localized to both the hypothalamus and the pituitary, it may have physiological significance in neuroendocrine immunology. As in the case of the other cytokines, both hypothalamic and pituitary sites of action may be of importance for the induction of changes in pituitary hormone release.

Therefore, although LPS does not alter pituitary hormone secretion directly, it induces cytokine release that in turn stimulates iNOS synthesis. The NO generated, together with the direct actions of the cytokines, produces modifications in the pituitary response to the altered pattern of hypothalamic peptides reaching the gland. Unfortunately, again, there have been no studies of these later events in terms of pituitary hormone release. From what is known, the general pattern that occurs immediately after the injection of LPS is maintained. Further studies of these later times are essential.

Role of Nitric Oxide in the Pattern of Pituitary Hormone Secretion in Other Physical and Psychological Stresses

In contrast to the extensive research carried out on the effects of LPS to mimic the effects of infection, little attention has been paid to the role of NO in mediating the effects of psychological stresses on the hypothalamic-pituitary axis. It has been shown that

restraint stress increases the expression of nNOS, but not iNOS, with the same time course and in the same regions in which LPS induces iNOS. Furthermore, the injection of nitroarginine methyl ester (L-NAME), an inhibitor of NOS, blocked ACTH release induced by foot shock and other physical-emotional stresses.

Effect of Infection on Cytokine and Nitric Oxide Formation in the Pineal Gland and in Other Organ Systems

Space limitations limit this article mostly to the effect of NO on the hypothalamic-pituitary axis; however, as described earlier, LPS causes the induction of IL-1 β mRNA followed by iNOS mRNA in the pineal as well, and experiments indicate that a similar response occurs in the heart and kidney. It is probably a uniform response throughout all organ systems of the body. Under normal conditions, NO exercises an important role in practically every, if not every, organ system of the body. The massive increase in NO production following infection is already known to be responsible for the production of toxic shock, and its toxicity probably contributes to the malaise that occurs during infections.

The Role of Nitric Oxide in Reproduction

Because LHRH induces ovulation by releasing LH and because animals go into heat around the time of ovulation, it occurred to me that LHRH could induce mating behaviour. Indeed, this turns out to be the case. Mating behaviour in female rats is brought about by LHRH neural axons that extend to the brain stem and release NO, which activates descending pathways and induces the lordosis reflex. Efferents from the pelvic spinal cord activate the pelvic ganglia, which send axons that extend to the corpora cavernosa of the penis and release Ach, which, in turn, acts on the muscle that releases NO, which activates GC to generate cGMP, which dilates the corpora leading to erection. In the presence of stress or infection, these pathways are inactive because stress blocks LHRH release. Viagra (sildenafil) promotes penile erection by inhibiting the phosphodiesterase 5 in the corpora cavernosa, thus slowing the inactivation of cGMP and prolonging the erection. The role of NO in mating behaviour is established, but its action in the external genitalia of women is not certain, although we predict that it would induce clitoral erection to facilitate orgasm.

The Nitric Oxide Hypothesis of Aging

As indicated earlier, NO generated by endothelial NOS (eNOS) and nNOS plays a ubiquitous role in

the body in controlling the function of almost every, if not every, organ system. Bacterial and viral products, such as bacterial LPS, induce iNOS synthesis, which produces massive amounts of NO toxic to the invading viruses and bacteria but also to host cells by the inactivation of enzymes leading to cell death. The actions of all forms of NOS are mediated not only by the free-radical oxidant properties of this soluble gas but also by its activation of GC, leading to the production of cGMP, which mediates many of its physiological actions. In addition, NO activates COX and LOX, leading to the production of physiologically relevant quantities of PGE₂ and leukotrienes.

The authors' hypothesis is that recurrent infections over the life span play a significant role in producing aging changes in all systems of the body via the release of toxic quantities of NO. NO may be a major factor in the development of coronary heart disease (CHD). Considerable evidence has accrued indicating

a role for infections in the induction of CHD and, indeed, patients treated with a tetracycline derivative had 10 times less complications of CHD than their controls. Stress, inflammation, and infection have all been shown to cause the induction of NOS in rats, and it is likely that this triad of events is very important in the progression of coronary arteriosclerosis leading to coronary occlusion. The aging of the anterior pituitary and pineal, with the resultant decreased secretion of pituitary hormones and the pineal hormone melatonin, respectively, may be caused by NO.

Inside the blood-brain barrier, the induction of iNOS in the temperature-regulating centers by infections may cause the decreased febrile response in the aged by loss of thermosensitive neurons. iNOS induction in the PVN may cause the decreased nocturnal secretion of GH and PRL that occurs with age, and its induction in the AN may destroy LHRH neurons, thereby leading to a decreased release of gonadotropins. Recurrent infections may play a role in the aging

Figure 1 Diagram of the mechanism of action of cytokines such as IL-2 to release CRH by nitric oxide. In the case of systemic administration of inflammatory cytokines such as IL-2 or pain stimuli, afferent input occurs by vagal afferents that project to the locus ceruleus, a small brain-stem nucleus that contains many norepinephrine neurons (NEn) that project axons to the PVN, where they are visualized to act on α_1 receptors (α_1R) on acetylcholine interneurons (Achn) there. When IL-2 is in the circulation, it can also reach these neurons and act on its receptors there (IL-2R) to activate the Achn. This releases acetylcholine (ACh) from synaptic vesicle ACh from the cholinergic neuron, which acts on muscarinic receptors (M-R) on the nitric oxide neuron (NON), increasing intracellular free calcium, which combines with calmodulin to activate nitric oxide synthase (NOS). This converts L-arginine within the neuron, which is also pumped into the neuron by an active transport mechanism in the presence of oxygen and various cofactors into citrulline (Citrul) and nitric oxide (NO) that diffuses over to the CRH neuron to activate guanylyl cyclase (GC), which causes the production of cGMP, which increases intracellular free calcium. The increased intracellular calcium not only plays a role in exocytosis of CRH granules, but also activates phospholipase A₂, which converts membrane phospholipids to arachidonic acid (AA). NO activates cyclooxygenase by interacting with the heme group on the molecule, leading to the conversion of AA to prostaglandin E₂ (PGE₂), which activates adenylyl cyclase (AC), which generates cAMP from ATP, which also leads to the extrusion of CRH synaptic vesicles into the hypophyseal portal veins (PV), which carry it to the anterior pituitary to release ACTH. CRHn, corticotropin-releasing hormone (CRH) neuron; mLipids, membrane lipids; NMDA, N-methyl-D-aspartic acid; PLA₂, phospholipase A₂.

of other parts of the brain because there are increased numbers of astrocytes expressing IL-1 β throughout the brain in aged patients. IL-1 and products of NO activity accumulate around the plaques of Alzheimer's disease and may play a role in the progression of the disease. Flu encephalitis during World War I possibly induced iNOS in cells adjacent to substantia nigra dopaminergic neurons, leading to the death of these cells, which, coupled with ordinary aging fallout, led to early-onset Parkinsonism. The CNS pathology in acquired immunodeficiency syndrome (AIDS) patients bears a striking resemblance to aging changes and may also be largely caused by the action of iNOS. Antioxidants, such as melatonin, vitamin C, and vitamin E, probably play an important acute and chronic role in reducing or eliminating the oxidant damage produced by NO.

Conclusion

NO clearly plays a very important role in mediating the response to stress of every organ system in the body. This article concentrates on its actions mediating the response to stress and infection of the hypothalamic-pituitary axis. Afferent input (e.g., by LPS acting on receptors on vagal afferents) reaches the brain stem, where it activates the locus ceruleus, an important nucleus containing neuroadrenergic neurons that project to the hypothalamus (Figure 1). In the case of the CRH-ACTH-adrenocortical axis, the NE released in the vicinity of the PVN activates CRH release by stimulating cholinergic interneurons that release Ach, which in turn activates NOergic neurons by muscarinic receptors. The NO released then triggers CRH release. LPS also acts on receptors in circumventricular neurons, such as the ME and organum vasculosum lamina terminalis, to activate the NOergic control of CRH release. CRH passes down the hypophyseal portal vessels and activates ACTH release. CRH releases ACTH from the corticotropes of the anterior pituitary gland, which circulates to the adrenal cortex to stimulate the release of cortisol. Cortisol exerts negative feedback to suppress CRH release and decrease the pituitary response to the CRH released. Continued stimulation by stress, such as LPS, maintains the stimulatory

drive, maintaining the elevated ACTH and cortisol concentrations.

Early Survey of Survivors of Violence
The Enniskillen Bombing
The Kegworth Air Disaster
Theoretical Model Used in Debriefing

Glossary

Posttraumatic stress disorder (PTSD) A psychological injury after violence, characterized by reexperiencing trauma, hyperarousal, and withdrawal.

Psychiatrists in Northern Ireland had been treating the survivors of violence for more than 10 years, since PTSD was defined in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III; 3rd edn.). In general psychiatry, most of the patients encountered are suffering from a psychiatric illness. This results when an individual who is vulnerable is subjected to a stressor. In the 1970s, the concept of psychological injury was not well developed, and so people who suffered from psychological problems after exposure to violence were viewed according to the psychiatric illness model. Either these patients were assumed to have some constitutional vulnerability to anxiety or depression and that a neurotic illness had been precipitated by an adverse life event or else the psychological injuries were dismissed as a normal reaction. Previous attempts to define psychological injuries, such as shell shock and combat neurosis, had been discredited because these diagnoses carried with them some secondary gain. In the early 1980s, a group of psychiatrists based at the Mater Hospital decided to examine the diagnosis of PTSD in order to see whether it applied to the victims of violence in Northern Ireland. The diagnosis had considerable appeal because of the clear operational definition involving a pattern of symptoms. However, local psychiatrists were skeptical about the diagnosis for three main reasons. First, community surveys in Northern Ireland had indicated that the number of cases of psychiatric morbidity in the province was no higher

than in England or Scotland. Second, experience with survivors of violence indicated that they were a very different population from the archetypal Vietnam veteran. In particular, there seemed little evidence of impulsive violence or substance abuse. And the final reason for skepticism about the diagnosis of PTSD was the fact that this diagnosis had already begun to fall into disrepute in the United States, where veterans of the Vietnam War were able to obtain a higher pension if they were given this diagnosis.

Early Survey of Survivors of Violence

This first study conducted in Northern Ireland had a simple methodology. The case notes of almost 700 patients were examined retrospectively, and for each case a total of 80 items of information were recorded. These 80 items of information included the symptoms of PTSD, social and environmental factors, and a number of other items that might be expected to predispose to psychological problems. The results of the survey were valuable because of the large number of patients involved and because the retrospective nature of this study (normally a disadvantage) meant that both the patients and interviewers were naïve to the diagnosis of PTSD and, thus, that the symptoms could not have been feigned. Eighty items of information were analyzed by the computer department of Queen's University, Belfast, where a mainframe computer applied the diagnostic criteria defined in DSM-III to the symptom checklists. The research team was surprised by the results.

Despite the skepticism of psychiatrists, when the diagnosis of PTSD was applied to this group of patients, 23% fulfilled the diagnostic criteria. This percentage is very high, especially considering that the symptoms of PTSD were not specifically being looked for at the time when the patients were interviewed. A number of factors were found to be significantly associated with the diagnosis. These findings were very much in keeping with literature on PTSD from other parts of the world, in that female, elderly, and unmarried individuals were more likely to develop PTSD. However, the negative findings were perhaps more striking than the positive findings. Despite the large numbers involved, there was no significant association of PTSD with a past history of psychiatric illness, family history of psychiatric illness, or any of the other putative vulnerability factors that were examined in this study.

It was also striking that 75% of the population had recovered from the psychological difficulties within 18 months. This indicated that most people had recovered before litigation issues had been settled. At that time, the conventional wisdom was the view of Millar, that psychological injuries do not resolve until compensation issues have been resolved.

The results of this study forced psychiatrists in Northern Ireland to reappraise their views on the psychological effects of violence. For the first time, PTSD began to be seen as a true psychological injury. Until then, it was not uncommon for victims of violence to be told by their doctors, "Of course, you're upset. It is normal to be upset when you have been involved in an explosion." Psychiatrists began to realize that saying this to patients was rather like saying to the victim of a road-traffic accident, "Of course, you've got a broken leg. It is normal to have a broken leg when you have been run down by a bus."

It was becoming clear that PTSD is an injury analogous to a grief reaction, in that it is a psychological reaction that happens to normal people when placed under extreme stress, and that there is a natural course of healing after such an injury which takes about 1.5 years. The analogy with grief reaction goes further in that certain circumstances at the time of the trauma might produce a delayed injury and that, if the natural course of the healing process is disrupted, a chronic injury may result. People in Northern Ireland were well aware that a grief reaction is normal and that allowances have to be made for normal people who suffer psychological problems for a year or so after a bereavement. Through a process of education, the public has become aware that psychological injuries after trauma do not imply any psychological weakness and that people with these injuries usually recover with the passage of time.

This study contained a large number of individuals with a wide spectrum of traumatic experiences, ranging from being a casual witness to a bombing to surviving a specific assassination attempt (e.g., one individual had survived an attempted sectarian murder; a gun was put to his head but jammed when the trigger was pulled). In addition, there were a number of individuals who experienced traumatic events unrelated to the Troubles, including common assault and sexual assault. When these different types of traumatic experience were grouped together, the researchers were surprised to find that there was no significant difference in the rate of PTSD among these different groups. It seemed that the seriousness of the traumatic event and the objective level of danger were less important in producing PTSD than the individual's subjective experience of the event.

The study raised a number of questions, which were addressed in a later study. A number of speculative suggestions have been put forward to explain the paradox that individuals affected by violence are psychologically ill and yet no increase in morbidity is seen in the community as a whole. The nature of violence in Northern Ireland changed during the 1970s from widespread civil unrest to attacks on specific targets. A much smaller number of individuals were involved in these violent incidents, and so community surveys might not be sensitive enough to pick up the small numbers involved. Anecdotally, psychiatrists noticed that the level of functioning of certain marginal individuals improved in an atmosphere of violence. It was believed that this might be because sectarian polarization had produced tightly knit ghettos with increased community spirit and support. Durkheim pointed out the importance of these social factors in determining the mental health of a community, and it might be that the detrimental psychological effects of violence for the individuals directly involved might be partly compensated for by the increased community spirit in tightly knit sectarian ghettos. The hypothesis was proposed that a blitz spirit in these communities might be masking the psychological ill effects on those directly effected by violence. If this is the case, it was proposed that, if the Troubles were to end and Northern Ireland returned to more normal social functioning, we might see an upsurge in psychological morbidity.

During the 1980s, a number of scientific papers were published describing survivors of various civilian disasters from all parts of the world. These papers emphasized the validity of the concept of PTSD. It was striking that the psychological sequelae seen after trauma were remarkably similar in different cultures and with different types of trauma. It became clear from the growing literature and from clinical experience that there is a core group of symptoms, involving hyperarousal, emotional constriction, and reliving the event, that are experienced after all types of trauma and that, in addition, to these symptoms there are a variety of other symptoms that depend on the type of trauma experienced. For example, passive victims of violence in Northern Ireland had low rates of substance abuse, survivor guilt, and acting as if the incident were reoccurring compared to active participants in violence such as Vietnam veterans. The survivors of hostage situations seemed to develop symptoms of learned helplessness in addition to the core syndrome of PTSD, and victims of sexual violence often suffered the additional symptoms of post-rape syndrome, including obsessional cleanliness, mistrust of members of the opposite sex, and an aversion to sexual stimuli. The definition of PTSD became more focused in

subsequent revisions of DSM-III, and the difference between the symptoms experienced by adults and children were more clearly delineated.

The Enniskillen Bombing

A terrorist bomb exploded in the town square at Enniskillen on Remembrance Sunday 1987 as the town gathered to remember the dead in two world wars. A group of survivors were followed up at 6 months and 12 months in order to determine the relationship between their physical and psychological injuries. Millar had said that there is an inverse relationship between physical injuries and psychological injuries after a traumatic event. This was found to be true when the survivors were followed up at 6 months, but at 12 months it seemed that those individuals who suffered more severe physical injuries tended to develop delayed PTSD after 6 months. This group of survivors were particularly unfortunate because their psychological injuries were only beginning to emerge at a time when other victims of the trauma were beginning to put the incident behind them. In working with survivors of the Enniskillen bombing, researchers emphasized the importance of local supports, debriefing, and education. Many survivors and their families were relieved to be told that the psychological reactions that they were seeing were, in fact, normal under the circumstances and were likely to improve within 18 months or so. Families were also relieved to hear that the withdrawal and irritability, which they were finding so hard to live with, were in fact predictable parts of a recognized psychological injury that tended to improve with time. In this way, education was able to prevent one of the main complications of PTSD, namely marital disharmony.

The Kegworth Air Disaster

A passenger jet carrying over 90 people traveling between London and Belfast in 1989 crashed on to a stretch of motorway as it was diverted to East Midlands Airport. Research teams followed up the survivors on both sides of the Irish Sea. The relationship between physical and psychological injuries was once more explored in some detail. One of the most striking findings from this piece of research, which was not reported in the original paper, was that individuals from England and Scotland (68%) were significantly more likely to develop PTSD than residents of Northern Ireland (43%) (Table 1). A number of possible reasons have been put forward to explain this result. It may be that even when applying the research criteria psychiatrists in Northern Ireland

Table 1 Rates of PTSD according to home address (%)^a

	<i>England/Scotland</i>	<i>Northern Ireland</i>
No PTSD	7	24
PTSD	15	19

^aPTSD, posttraumatic stress disorder.

tend to be more reluctant to make the diagnosis of PTSD, perhaps applying the research criteria more strictly than our colleagues in mainland United Kingdom. Another possible reason is that individuals living in Northern Ireland have been in some way inured to violence and were, therefore, less traumatized than individuals from mainland United Kingdom, who had less direct experience of traumatic situations. Anecdotal experience indicates that individuals may suffer a series of traumatic events without any psychological ill effects, only to break down very severely after a relatively minor trauma. This suggests that repeated exposure to trauma can strengthen defense mechanisms up to a certain point, but once these defense mechanisms have been overwhelmed the psychological injury seems more severe than otherwise would be the case.

Theoretical Model Used in Debriefing

Successful debriefing seems to depend on making PTSD understandable to the individual involved. Models that are too technical or difficult to believe are of little value. The following model has been developed from various sources, as well as from direct experience of PTSD in Northern Ireland.

Three groups of symptoms are involved in PTSD: hyperarousal, reliving the incident, and emotional constriction. The hyperarousal is best explained as part of the fight-or-flight response to stress. This is one of the survival mechanisms by which nature has equipped us to deal with dangerous or threatening situations. Symptoms such as increased aggression, increased startle reaction, sleep disturbance, and hypervigilance are seen. These symptoms may improve an individual's chances of survival in a dangerous situation and arguably improve the functioning of a combat soldier.

The symptoms of reexperiencing the incident in the form of flashbacks and nightmares is best understood according to Janet's model of traumatic memory. Under normal circumstances, long-term memories are laid down in a process of digesting experience. Long-term memory is not a factual record of events but a story that we tell ourselves to explain the past. It seems that traumatic memories are portions of experience so threatening to the individual that they

cannot be digested by this process. In this way, the traumatic event remains recorded as a factual record, almost like a videotape. Individuals can remember what they had for breakfast on the day of a traumatic event 15 years after the incident. Perhaps this is why listening to the accounts of survivors is so distressing – the events are recorded so literally and usually accurately. These traumatic memories are so distressing that they are phobically avoided. They are suppressed, and the conscious mind attempts to keep them in the subconscious. However, they reemerge when the individual is off-guard (e.g., when asleep). It may be that it is this phobic element that is improved when individuals undergo eye movement desensitization.

Emotional constriction and estrangement from others can be viewed as a loss of innocence. This assumes a state of normal denial, in which most people believe that the world is a safe place and that death and mutilation are things that happen to other people. However, traumatic events force us to confront our own mortality and destroy this normal denial. Thus, people with PTSD are living in a different – more dangerous – world than those individuals around them, who continue to convince themselves that the world is a safe place. In order to be normal again, individuals with PTSD must convince themselves once more that the world is a safe place, and they attempt to do this by suppressing the memory, thus leading to the development of traumatic memories that reemerge in the form of nightmares and flashbacks.

This model has been found to be very useful in talking to survivors of violence. People with PTSD often think of themselves as members of an elite club who are able to see the truth when those around them remain naïve. It is perhaps for this reason that group therapy can be successful in PTSD, although there is a strong danger of scapegoating in groups because of the high levels of free-floating anger that survivors suffer as part of PTSD.

The Clinical Resource and Efficacy Support Team for Northern Ireland reviewed the Northern Ireland literature and produced guidelines for management of PTSD in June 2003. This found strong evidence that a single-session individual debriefing was not helpful and may well be harmful. The team also found evidence that brief programs of cognitive-behavior therapy were effective, as well as pharmacological treatment with selective serotonin reuptake inhibitors (SSRIs), monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants (TCAs). Eye movement desensitization and supportive group therapy were also found to be effective, and there was evidence that nonprofessional and practical assistance reduced the frequency of avoidance and intrusion symptoms.

Because individuals with PTSD are normal, they often do not respond well to mental health professionals. Normal supports are more useful in supporting these individuals (e.g., family, friends, employment, and church), but debriefing and education are useful in reducing the suffering for survivors and their families. Symptomatic relief can be offered, but, if PTSD persists beyond 1.5 years, the prognosis becomes less positive and the response to treatment is usually incomplete, leaving lasting emotional scars.

Threat of Nuclear Warfare

Evaluating the Threat

Questionnaires: The Chief Method of Studying
Nuclear Anxiety

Individual Studies

Summary

Glossary

<i>Anxiety</i>	The fearful anticipation of potential harm.
<i>Denial</i>	A concept of psychoanalytic origin implying an unwillingness to face unpleasant facts.
<i>Questionnaire</i>	A French word, meaning a list of questions, usually on a particular subject of psychological interest, with a common restricted format for answers. If properly standardised and validated on relevant populations they can be useful in estimating psychological characteristics and states of mind.

Threat of Nuclear Warfare

One thing can be said for certain about nuclear anxiety – it is not an innate fear. On the contrary, no other anxiety depends so much on an appreciation of a wide range of political, cultural, and military threats. Anxiety about the threat of nuclear warfare is caused by the belief that a nuclear war may happen and that it will bring widespread destruction to civilization. This anxiety is linked to powerful images of the explosive power of nuclear weapons and to the dreadful consequences for individuals, society, and the environment if they should come to be used. If all anxiety is based on an assessment of threat, even though the assessment may be faulty, then anxiety about nuclear war is threat assessment at its most difficult.

Evaluating the Threat

A balanced, rational assessment of the threat of nuclear war includes assessing the following issues:

the destructive power of the weapons, the reliability of the weapons-delivery systems, the protection afforded by buildings and shelters, the viability of countermeasures, the extent of the damage caused by the weapons to national infrastructure, the effects of radiation, the effects of major fires on the climate, the possibilities of reconstruction, the nature of enemies, the international political scene, the personalities of the nuclear weapons operators and political leaders, the mood of people in countries that have nuclear weapons, the reliability of warning systems, the possibilities of false alarms, the likelihood of terrorist actions, and the spread of nuclear weapons capability to other nations and to armed groups. By the very nature of the threat, such a list can never be exhaustive. To complicate matters, nuclear weapons are now often categorized as weapons of mass destruction, so the risks are conflated with chemical and biological warfare risks. A less rational assessment of the likelihood of nuclear war is subject to the distorting effects of personal depression, selective monitoring of news, paranoid ideas about other nations, and generalized sociopolitical anxiety.

As a consequence, any proper evaluation of the topic must contrast the objective threat with the perceived threat and then explain any identified differences. In fact, it has been extremely hard for the average citizen to evaluate this threat, which has been with us in various forms for over 50 years. Much of this uncertainty relates to the secrecy that has surrounded nuclear warfare and to the difficulty of determining the intentions of opposed nations.

One approach to getting a more objective assessment is to look at the Doomsday Clock, which was established by the *Bulletin of the Atomic Scientists* in 1947 as a way of showing the consensus view of scientists of the likelihood of nuclear war. Assuming for the moment that these scientists know more about the risks than the average person, the highest danger point, at 2 min to midnight, came in 1953 with the hydrogen bomb tests. The next closest, at 3 min to midnight, came in 1949 when the Soviet Union exploded its first atomic bomb and in 1984 when the arms race accelerated. By 1991 the clock had achieved a safety high point, with a leisurely 17 min to midnight, as arms reductions took place and the Soviet Union contracted. It currently stands at 7 min to midnight, unchanged since February 2002 as a consequence of political extremism and the proliferation of weapons.

There is little doubt that the destructive power of nuclear weapons is very great and has increased

greatly over successive decades. However, many citizens find it difficult to comprehend the destructive power of these weapons, which is so far outside normal human experience, and at the same time may incorrectly believe that everything will be destroyed during a nuclear war. Although it is very hard to be sure about the consequences, there are a range of possibilities.

A full-scale nuclear war might destroy some nations immediately by so damaging their cities and infrastructures that it renders them incapable of providing basic services to their citizens, in the same way that conventional wars have damaged many parts of the world and left the local population destitute, without shelter and food, and dependent on outside help for survival. Such a general world war with nuclear weapons could well leave the survivors incapable of maintaining themselves at their former level of living, in the way that the Black Death disrupted the medieval world. Strategists argue as to whether it would be possible to have a limited nuclear war, many feeling that a nuclear war would quickly spread out of control.

However, from the perspective of the beginning of a new century, the threat of the immediate destruction of civilization may seem remote. The end of the cold war has brought about a change of mood as well as a change in the real level of threat of war between superpowers. Nuclear weapons have come to be seen as an ancient terror, last year's music. Yet the number of nuclear nations has grown, and the threat of regional nuclear conflicts has increased. It would indeed be a cruel fate for our global society to perish from an unfashionable cause.

Questionnaires: The Chief Method of Studying Nuclear Anxiety

Where would the study of anxiety be without the questionnaire? No other method in the social sciences has borne so heavy a load and has been pressed into service in so many campaigns and in so many different theatres of research. The procedure is as follows. The authors make a list of questions to which they would like answers, sometimes drawn from their own interests and imaginations, sometimes drawn from matters of public debate, and even sometimes drawn from opposed points of view. The answers given by willing subjects are often reported in raw form by giving the percentages of respondents who agree with a particular proposition. Sometimes the question list is subjected to item analysis to detect faulty questions and to factor analysis in order to search for an underlying structure to the answers. This generally

leads to revisions of the question list and the methods for scoring the answers to produce subscores with greater explanatory power. The questionnaire is now judged fit for wider use, and comparative studies follow with different populations. Done well, this can be a considerable help in understanding the answers to the questions and can produce interesting comparisons between different groups. Done badly, it can produce many ineffective lists of questions leading to a confusing mass of contradictory findings.

A more profound problem with questionnaires is trying to understand what questionnaire responses really mean. Do they tap real opinions that may lead to real actions, or are they little more than party chatter, the surface moods and immediate responses of the disengaged? In plain terms, is a person who says he or she is anxious about nuclear war really anxious about nuclear war, and what does the person's anxiety amount to? Does it restrict the person in the way that a phobia might? Does the person experience the agony of someone who fears flying but must travel by air for some urgent reason?

To answer those questions, the questionnaire approach must be supplemented with appropriate observations and suitable cross-checks. So, if someone is anxious that there will be a nuclear war, how will he or she behave? If the person believes that war is imminent, some of his or her behaviors ought to be obvious, but if the person cannot be sure how soon the war will start, then it is harder to make predictions. We might surmise that the person would be less likely to make long-term investments and preparations, that he or she would have some sort of emergency nuclear war plan, and that he or she would frequently refer to possible nuclear wars when contemplating all other plans. Such behavioral indicators of nuclear anxiety have been studied infrequently.

The typical subjects of questionnaire studies are captive student populations, although occasionally a proper epidemiological sample is obtained. The ages of the subjects are generally 11 and above, and usually the subjects are tested on one occasion, without much reference to other measures such as intelligence, personality, medical history, school records, spare-time activities, and other interests. Although some questionnaires are used in comparative studies, question lists tend to proliferate and to tap different domains, and often they advertise their purpose in a way that may influence the answers that respondents give. For example, people may be moderately optimistic until faced with a list of dangers and then they become more fearful as they contemplate

all the threats that face them. The demand characteristics of the questionnaire may lead to self-serving distortions.

Individual Studies

Nuclear Warfare Anxiety

The category of nuclear warfare anxiety may contain a number of related fears. These include fears about death, from whatever cause; worries about the dangers of technology and the pace of change in industrial societies; despair at not being able to bring about political change on the nuclear weapons issue; and a general sense of foreboding about the future. Nonetheless, when questionnaires are appropriately refined, nuclear weapons can be shown to be a cause of anxiety in their own right.

How Common Is Nuclear Anxiety?

In the 1980s and early 1990s, nuclear anxiety was common. It was generally cited as being in the top three worries of most young people, although the rate declined as the cold war diminished. The death of parents, doing very badly at school, getting cancer, and being unemployed were the other most common worries. The mid-1980s seem to have been the peak, with as high as 54% of U.S. and 93% of USSR adolescents responding that they were worried about nuclear war. A few years later, the rates had diminished by approximately 10%. Large-scale epidemiological studies show big variations in the rates, with as high as 80% of Finnish adolescents and as (relatively) low as 30% of English and Austrian adolescents reporting such fears. Interestingly, most of the literature on this subject dates from before 1993; after that year, there are far fewer published findings.

Who Is Affected by Nuclear Anxiety?

Most people are affected by nuclear anxiety to some extent. Despite some early anxieties about biased questionnaire samples, nuclear anxiety is not restricted to wealthy, politicized families but is found in all social strata, including profoundly disadvantaged teenagers living in violent inner-city neighborhoods (who might be thought to be too much at present risk to worry about future dangers). In this last group, despite not having activist parents and despite personally despairing about being able to do anything about the nuclear threat, teenagers ranked nuclear war (in 1991) as their second worry – after fear of being murdered – and this fear was higher in those who had actually experienced violence.

Those with nuclear anxiety tend to be more aware of global issues; have good self-esteem; believe that they, and not outside forces, are responsible for their success in life; be not unusually anxious in general; be not religious; have a healthy optimism about the future; and have a tendency toward political activism. Women generally are more likely than men to experience nuclear anxiety.

Does Nuclear Anxiety Run in Families?

The few studies that matched children with their parents found an understandable similarity of attitudes. Nuclear concern is higher in higher-income families; scholastically able children are more knowledgeable and more fearful about nuclear war; and children's hopelessness about the arms race increases as parents' worry about nuclear war increases. Girls express more worry than boys. Interestingly, children with a high degree of general anxiety do not indicate a high degree of nuclear fears. However, parents are often poor at predicting nuclear anxiety in their children and are more likely to deny their own anxiety than are their children.

How Do People Cope with Nuclear Anxiety?

One coping mechanism is to downplay a real anxiety. Keilin sought to go beyond questionnaire studies by subjecting those who reported themselves to be high or low on nuclear anxiety to a laboratory investigation of their emotional responses to nuclear images. People with low nuclear anxiety, although reporting lower levels of emotionality, were more emotional when shown nuclear war stimuli, as reflected by several physiological and behavioral measures. People with high nuclear anxiety were also anxious about relevant social issues, but did not have a greater disposition to be anxious. Keilin interpreted these findings as supporting the existence of nuclear war-related denial processes on the part of the low-anxiety-reported group but only when faced with highly salient and dramatic nuclear stimuli. So, some people repress their nuclear anxieties and others sensitize themselves to the emotional threat, and questionnaires may pick up their preferred coping styles rather than their real emotions.

Another approach is to become an activist. Peace activists sometimes find that their initial anxiety about nuclear war subsides after they have been active for a period of time. They see activism as intrinsically valuable, something they turned to at periods of flux in their lives, believing that they should act to prevent current problems caused by the arms race and not just the anticipated damage from a nuclear war.

How Do the Nuclear Anxious Differ from Others?

Anti-nuclear activists tend to be cooperation-oriented individuals who express spontaneous nuclear concern, have high nuclear anxiety, and also have feelings of empowerment on personal and nuclear issues. They possess feminine traits and are generally tolerant of ambiguity, are open-minded, and have low manipulative tendencies in interpersonal relationships. They are likely to believe that chance does not determine nuclear outcomes and that nuclear war cannot be survived. The most common contrasting group has been those who are pro-defense, that is to say, those who believe that the best protection against nuclear war is to hold nuclear weapons as a deterrent. Pro-defense activists tend to be strength-oriented individuals who express low nuclear anxiety and tend to be masculine, dogmatic, persuasive, and intolerant of ambiguity. They are likely to believe that nuclear issues are controlled by powerful others and chance. This is a very clear differentiation between attitudes and suggests a profoundly different worldview, leading to widely differing rates of nuclear anxiety.

Does Nuclear Anxiety Cause Psychological Disorders?

Specific anxiety about nuclear war does not appear to lead to psychological disorders, although despair about the future (which may show up as nuclear anxiety on general questionnaires) may be linked with adolescent depression. Those with nuclear anxiety followed up 8 years later were very slightly more likely to have psychosomatic health complaints and

emotional distress but not drug, relationship, or work problems.

Summary

Nuclear anxiety appears to be somewhat different from more trait-based stress conditions in that it is a reaction to real-world events and it seems to have subsided with the passing of the cold war. In terms of the usual imperfect measures, it appears that children survived their upbringing in the nuclear age. Although it is hard to prove identifiable major effects of nuclear anxiety, it would be surprising if so widespread a perceived danger had no effect at all. Perhaps the main effect has been to frighten many, to reduce their confidence in the future, and to goad some into activism, leading to considerable relief for all when the arms race ended in a truce.

Introduction

Stress-Induced Eating: the Tail-Pinch Model

Stress-Induced Anorexia

Anorexia of Aging: a Response to a Physiological Stressor

Stress, Chewing, and Feeding in Humans

Conclusion

Glossary

Corticotropin-releasing hormone (CRH)

A neurotransmitter that plays a role in co-ordinating the response to stress. Administration of CRH causes anorexia, and it appears to be the major neurotransmitter responsible for stress-induced anorexia.

Stress-induced anorexia

Decreased food ingestion secondary to a severe stressor that can be either exteroceptive or interoceptive.

Stress-induced eating

Eating induced in response to an external stressor.

Tail-pinch eating

Eating induced in rodents or cats by gently pinching their tail. It is mainly due to activation of an endogenous opioid, dynorphin.

Introduction

There are numerous interactions between stress and nutrition. Nutrition insecurity is one of the most important stressors of the human race. The need to maintain nutritional intake is the primal driving force of human beings. Simple organisms, such as the *Pleurobranchia*, spend the majority of their life eating and only when adequately nourished (their state of eustress) do they release a satiety hormone that stops eating and then results in egg laying. Severely malnourished women lose the ability to produce luteinizing hormone surges and become amenorrheic. Malnutrition leads to immune dysfunction, including a marked decline in CD4+ T lymphocytes producing a similar picture of immune function to that seen in patients with AIDS. Malnutrition increases the propensity of organisms to develop a variety of infections, which, with associated cytokine release, lead to activation of the stress response. Thus, deficient nutritional intake can be associated with both psychological and physical stressors.

Much of the long-term injury produced by repetitive stress is due to damage produced by free radicals.

A number of nutrients such as vitamins C and E and the trace mineral selenium play an important role as free radical scavengers and as such may limit stress-induced damage.

In addition to the effects of nutrition as a stressor and stress alleviator, an important component of the stress response is alterations in food ingestion. Dependent on the kind and duration, stress can either increase or decrease food intake. A number of psychiatric diseases, such as depression and anorexia nervosa, produce alterations in food intake secondary to activation of the classic stress response. Obesity, which has become a national epidemic in the United States, has been associated with a variety of psychological stressors in relationship to the alteration in body image. Release of stress hormones, such as cortisol, can alter fat deposition, resulting in an increase in visceral obesity. Visceral obesity is associated with an increase in diabetes mellitus, hypertension, myocardial infarction, stroke, and mortality. Aging is a physiological stressor that is associated with anorexia.

Figure 1 summarizes the potential interactions between nutrition and stress.

Figure 1 Nutrition and stress interrelate at multiple levels. Nutritional factors can produce stress and stress can lead to under- or overnutrition. Eventually a vicious cycle develops. CRF, corticotropin releasing factor, synonymous with CRH, corticotropin-releasing hormone.

Stress-Induced Eating: the Tail-Pinch Model

Stress-induced ingestion has been classically described in the ethology literature. Eating is commonly observed during boundary disputes in a variety of birds. Pecking at the ground is common, and the frequency can be increased experimentally by replacing the substratum with grain. Cichlid fish bite at the substratum during intervals between fighting. Electric shocks given to sticklebacks result in feeding similar to that seen with food deprivation. Handling rats may increase food intake. Electric shocks induce chewing in monkeys and rabbits. These findings led researchers to develop a stress-induced eating model, namely mild tail pinch in cats, rats, and mice. The stressor appears to be the pinch as a mild pinch to other parts of the body also induced feeding.

The tail-pinch model represents a stimulus-bound behavior in that the rodent stops eating as soon as the pinch is removed. The phenomenon generalizes to sweetened milk but not to water ingestion. Tail pinch appears to drive chewing to a greater degree than it drives ingestive behaviors. Tail pinch may also induce other behaviors such as copulation and maternal behaviors. Tail pinch demonstrates a number of similarities to the behavior seen following electrical stimulation of the lateral hypothalamus.

The neurochemistry involved in tail pinch-induced eating has been explored in some detail with pharmacological approaches. Both dopamine and endogenous opioids appear to play a central role in the modulation of tail-pinch eating. Dopamine appears to be involved predominantly in the production of chewing behaviors, whereas opioids appear to be more involved in ingestive behaviors.

A number of neurotransmitters and peptide hormones have been shown to decrease tail pinch-induced ingestive behaviors. Centrally, these include serotonin, prostaglandin E₂, and thyrotropin-releasing hormone. Peripherally, both cholecystokinin and bombesin decrease food intake in the tail-pinch model.

Prolonged chronic tail pinch eventually results in weight loss and naloxone-perceptible withdrawal symptoms. These animals show similar changes to those seen in morphine-addicted animals.

In summary, tail pinch-induced eating appears to be an excellent model of stress-induced eating, which is predominantly dependent on the activation of dopaminergic and opioid neurotransmitters.

Stress-Induced Anorexia

Severe stressors, such as restraint stress, in rodents result in anorexia and weight loss. Corticotropin-releasing hormone (CRH) has been demonstrated

to be a potent anorectic agent when administered intracerebroventricularly to rodents. CRH levels increase in the hypothalamus during restraint stress. Inhibition of CRH with antibodies or antagonists reverses the anorexia associated with restraint stress.

Anorexia produced by CRH can be attenuated by tail pinch, suggesting a delicate balance between stress-induced eating and stress-induced anorexia.

Overall, considerable evidence shows that stress-induced anorexia is due to the activation of CRH. CRH also appears to play an important role in stress-induced anorexia in humans (*vide infra*).

Anorexia of Aging: a Response to a Physiological Stressor

The aging process can be conceived to be a physiological stressor that produces its effects over the life span. Over the life span there is approximately a 30% decrease in food intake. This is predominantly due to a decrease in the central opioid-feeding drive. There does not appear to be an alteration in the effects of CRH with aging. In addition to the central neurotransmitter changes with aging, there are also peripheral alterations in adaptive relaxation of the fundus of the stomach due to decreased nitric oxide synthase activity. This leads to early antral filling and a greater degree of satiation for a given amount of food ingested.

The anorexia of aging makes the older individual at greater risk for developing severe anorexia and weight loss when exposed to stressors. The release of cytokines from varying sources has a potent anorectic effect in older persons secondarily to activation of the CRH stress cascade.

Stress, Chewing, and Feeding in Humans

Stress has long been recognized as a cause of masticatory muscle contraction. As pointed out by St. Matthew, "and there shall be a weeping and gnashing of teeth." Biting into a hard object was used by early surgeons to decrease the pain of surgery in the days antedating anesthesia. Anxiety increases bruxism (tooth grinding). In Lesch-Nyhan syndrome (hypoxanthine-guanine phosphoribosyltransferase deficiency), oral stereotypy is increased markedly during periods of emotional distress.

In humans, approximately two-thirds become anorectic when stressed, whereas one-third overeat. In stressed overeaters the act of chewing appears to be as important as the actual ingestion of food. When the stressor is boredom, overeating is the most common associated behavior. Bulimia (binge eating, which may be associated with subsequent vomiting) is often precipitated by a traumatic event.

Anorexia nervosa represents a classic pathological example of intrapsychic stress resulting in anorexia and severe weight loss. Patients with anorexia nervosa have been demonstrated to have elevated CRH levels in the cerebrospinal fluid.

Depression represents a major intrapsychic stressor. Two-thirds of depressed persons tend to be anorectic, and in these individuals, CRH levels in the cerebrospinal fluid are increased.

Conclusion

There is now ample evidence that not only does nutritional insufficiency result in stress, but stressors can lead to either over- or undereating in human beings. Both the endogenous opioid system (dynorphin) and CRH have been demonstrated to be neurotransmitters playing a role in the alterations in ingestive behavior produced by stress. A number of diseases that have a predominant component of altered food ingestion, such as anorexia nervosa and bulimia, appear to be precipitated by stress. Nutrient intake remains the most important behavior for the survival of all organisms. It is not surprising, therefore, that nutrition and stress are intertwined so intimately.

CONTENTS BY SUBJECT AREA

ANIMAL STUDIES AND MODELS

- Animal Models (Nonprimate) for Human Stress
- Circadian Rhythms, Effects of Prenatal Stress in Rodents
- Fish, Stress in
- Immobilization Stress
- Pre-pulse inhibition
- Primate Hierarchies and Personality
- Primate Models, Behavioral-Immunological Interactions
- Primate Models, Cardiovascular Disease
- Primate Models, Overview
- Primates: Rearing and Effects of Stress on Primate CNS Function
- Sex-Specific Effects of Early Social Stress in Mammals: a Study in Guinea Pigs

CONFLICT, WAR, TERRORISM

- Chemical Warfare
- Gulf War Syndrome, Psychological and Chemical Stressors
- Hiroshima Bombing, Stress Effects of
- Holocaust, Stress Effects of
- Impact of Terrorism on the Development of Mental Health Symptoms
- Korean Conflict, Stress Effects of
- Lockerbie Air Crash, Stress Effects of
- Northern Ireland, Post Traumatic Stress Disorder in
- Nuclear Warfare, Threat of
- Oklahoma City Bombing, Stress Effects of
- Persian Gulf War, Stress Effects of
- Prisoners of War
- 9/11, Religion and Stress
- Suicide Terrorism, Genesis of
- Terrorism
- Torture

- Traumatic Stress and Posttraumatic Stress Disorder; the Israeli Experience
- Vietnam Veterans, Postwar Experiences and Health Outcomes
- War Stress in the Former Yugoslavia
- War, Suicide and Sacrifice

DISASTERS

- Airline Accidents
- Chernobyl, Stress Effects of
- Disasters and Mass Violence, Public, Effects of
- Disaster Syndrome
- Earthquakes, Stress Effects of
- Floods, Stress Effects of
- Hurricane Katrina Disaster, Stress Effects of
- Motor Vehicle Accidents, Stress Effects of
- Three Mile Island, Stress Effects of

DIURNAL, SEASONAL AND ULTRADIAN RHYTHMS

- Circadian rhythm effects on cardiovascular and other stress-related events
- Circadian Rhythms, Genetics of
- Night Shiftwork
- Seasonal Changes in Stress Responses
- Seasonal Rhythms
- Sleep Loss, Jet Lag, and Shift Work
- Sleep, Sleep Disorders, and Stress
- Ultradian Rhythms

DRUGS (EFFECTS)

- Alcohol, Alcoholism and Stress:
A Psychobiological Perspective
- Drug Use and Abuse
- Interactions between Stress and Drugs of Abuse
- Opioids

DRUGS (TREATMENT)

- Antipsychotic Drugs and Stress
- Anxiolytics
- Benzodiazepines
- Beta-Adrenergic Blockers
- Pharmacological Treatments of Stress
- Selective Serotonin Reuptake Inhibitors (SSRIs)
- Stress and Anxiety: treatment with 2nd generation antipsychotic drugs

GENERAL CONCEPTS AND MODELS

- Alarm Phase and General Adaptation Syndrome
- Allostasis and Allostatic Load
- Behavior, Overview
- Conservation of Resources Theory
- Control and Stress
- Demand–Control Model
- Effort–Reward Imbalance Model
- Environmental Factors
- Evolutionary Origins and Functions of the Stress Response
- Fight-or-Flight Response
- Instinct Theory
- Life Events Scale
- Psychological Stressors, Overview
- Remodelling of neuronal networks by stress
- Selye, Hans
- Stress, Definitions and Concepts of
- Stress Effects, Overview
- Stress System Balance Hypothesis
- Stress, Beneficial Effects of

GENETICS AND GENOMICS

- Circadian clock genes as modulators of sensitivity to genotoxic stress
- Corticosteroid Receptor Genes: Functional Dissection in Mice
- Corticotropin Releasing Factor Receptor Deficiency in Mice
- Drosophila Genes and Anoxia
- Expression Profiling of Stress Responsive Gene Patterns
- Gene Environment Interactions in Early Development
- Genetic Factors and Stress
- Genetic Polymorphisms in Stress Response
- Genetic Predispositions to Stressful Conditions
- Genetic Testing and Stress
- Genetic variation of HPA axis activity and function in farm animals
- Glucocorticoid Receptor Mutant Mice as Models for Stress-Induced Affective Disorders

- Glucocorticoid Receptor Mutations and Polymorphisms
- Mineralocorticoid Receptor Polymorphisms
- Neuroticism Genetic Mapping of
- Neuroticism Response to Stress, Genetic Mapping of Mice
- Serotonin Transporter Genetic Modifications
- Strain Differences in Stress Response in Rodents
- Stress and CNS Arousal; Genomic Contributions

HUMAN COGNITION, EMOTION AND BEHAVIOR

- Adolescence
- Aggression
- Aggressive Behavior
- Aging and Psychological Stress
- Anger
- Anxiety
- Bereavement
- Burnout
- Captivity, Adaptation to
- Captivity, Recovery from
- Caregivers, Stress and
- Childbirth and Stress
- Cognition and Stress
- Combat, Acute Reactions to
- Combat Reaction, Chronic
- Combat Stress Reaction
- Concentration Camp Survivors
- Coping Skills
- Coping and Stress: a Lens and Filter Model
- Cortisol Awakening Response
- Death Anxiety
- Dental Stress
- Depersonalization: Systematic Assessment
- Diet and Stress, Non-Psychiatric
- Dissociation
- Distress
- Emergency Personnel, Stress in
- Emotional Inhibition
- Emotions: Structure and Adaptive Functions
- Fatigue and Stress
- Fear
- Fear and the Amygdala
- Firefighters, Stress in
- Grieving
- Holocaust Survivors, Experiences of
- Homosexuality, Stress and
- Hostility
- Impotence, Stress and
- Impulse Control
- Industrialized Societies
- Learning and Memory, Effects of Stress on
- Marriage

Medical Profession and Stress
 Memory Impairment
 Menopause and Stress
 Neuroimaging and Emotion
 Nightmares
 Optimism, Pessimism and Stress

PREFACE TO FIRST EDITION

“Stress” remains one of the most frequently used but ill-defined words in the English language. Stress is a phenomenon that has quite different meanings for the politician, social scientist, physician, nurse, psychotherapist, physiologist, molecular biologist, and perhaps you and me. This diversity of meanings was one impetus for creating the *Encyclopedia of Stress*, the aim being to derive a definition of stress from a variety of expert descriptions. The second impetus was the obvious need for an up-to-date compendium on one of the most important social, medical, and psychological phenomena of our age. We were fortunate in attracting stars for our Editorial Board and a set of most distinguished contributors for the 400 or so entries—indeed, the list of contributors is a Who’s Who in stress research.

We anticipate that the diversity of our readers will equal the diversity of the topics covered. They will find that the coverage of the Encyclopedia extends well beyond the general adaptation theory of Hans (Janos) Selye and the fight-or-flight response of Walter Cannon. Nevertheless, the general principles annunciated by these two great pioneers in the field still underpin our understanding of the biology of the stress phenomenon. That is, stress is a real or perceived challenge, either endogenous or exogenous, that perturbs body equilibrium or “homeostasis.” The stressor may range from overcrowding, traffic congestion, violence, bereavement, redundancy, or unemployment to physical, chemical, biological, or psychological insults. Whether the person can adapt to or cope with the stress will depend on the nature and severity of the stressor and the person’s physical and mental state, which in turn depends on genetic, experiential, social, and environmental factors. These issues are discussed in depth in the Encyclopedia, as are the mechanisms of coping and the impact of stress on health and predisposition to diseases such as

cancer, infection, rheumatoid arthritis, heart disease, high blood pressure, and mental disorder.

Aggression remains a hallmark of human behavior, even as we move into the third millennium, and so the Encyclopedia covers several topical areas that have only recently been analyzed systematically. These include war and specific wars, posttraumatic stress disorder (PTSD; formerly thought of vaguely as “shell shock”), rape, torture, marital discord and spousal abuse, and the Holocaust. In tackling these topics we accept that our entries may not include all the nuances that are necessary for a full understanding of what these phenomena are all about and described so graphically and sensitively in Tolstoy’s *War and Peace* or Pat Barker’s monumental *Regeneration* trilogy on the horrific psychological traumas of the First World War. Nevertheless, an important start has been made in that we now accept that PTSD is not just a lack of “bottle” (courage or “guts”), but rather a syndrome that needs to be and can be understood within the framework of medicine and psychology.

Biologically, the stress response reflects a set of integrated cascades in the nervous, endocrine, and immune defense systems. As in most areas of biology, molecular genetics has made a significant difference in the precision with which we now understand the physiopathological processes of the stress response. And so the adage formerly applied to diabetes mellitus may now apply equally to stress: “Understand stress and you will understand medicine.”

In summary, we hope that this first *Encyclopedia of Stress* will indeed define the phenomenon and at the same time provide a valuable source of information on a phenomenon that affects us all. In setting out on this adventure we were aware that there is nothing new under the sun and that stress has been around since the first biological particles, bacteria, or even viruses competed for the same mechanisms of replication.

There is a tendency for each generation to imagine that stress and its untoward effects are uniquely harsh for them, but it is not this misconception that underlies this work. Rather, the stress of “stress” itself—the massive accumulation of knowledge—made it seem propitious to bring the information together in a systematic manner that allows ready access to all who need or wish to understand the phenomenon.

The idea of producing this Encyclopedia was conceived at an Academic Press reception in San Diego held in conjunction with the annual meeting of the Society for Neuroscience in 1996. I am deeply indebted to Erika Conner for enabling conversion of the idea to a concept and then a project and to

Jennifer Wrenn, Christopher Morris, and Carolan Gladden, all of Academic Press, for their enthusiasm, encouragement, and herculean efforts that converted the concept into a reality. For giving generously of their intellect, expertise, sound advice, and unstinting work, I am greatly indebted to my friends and colleagues on the Editorial Board, who made the project such a satisfying experience. To all our contributors go our profound thanks for taking time out from wall-to-wall schedules to produce their entries, which together have made this Encyclopedia.

George Fink
August 1999

PREFACE TO THE SECOND EDITION

The popularity of the first edition of the Encyclopedia of Stress, the several major stressful conflicts that have occurred since 1999, and the significant advances in our knowledge of stress prompted the production of this second edition. In addition to more than 140 new articles, most of the original 400 first edition articles have been updated for the second edition to reflect, for example, advances in our understanding of corticotropin releasing factor (CRF) and urocortin receptors, ideas about the role of central CRF in the overall control of the psychological/mental as well as neuroendocrine response to stress, and the novel discoveries of the complex neuropeptide regulation of hunger and satiety. The effects of maternal and perinatal stress on subsequent body development and function in the adult, the adverse effects of stress on brain (and particularly hippocampal memory function), the role of the amygdala in fear and aggression, and the role of stress in the etiology of obesity and the metabolic syndrome all feature prominently in this new edition. 9/11 and the many new conflicts since 1999 have engendered new articles on terrorism, suicide bombers and their effects, as well as a retrospective on previous human apocalypses such as Hiroshima. Coverage of the whole field of post traumatic stress disorder (PTSD) has been expanded, reflecting the greater recognition and understanding of PTSD, and possibly related disorders such as *combat fatigue* and *burnout*. Stress and depression and anxiety, already touched on in the first edition, now feature prominently. On the conceptual side, *allostasis* (modified from Hans Selye's *heterostasis*), or stability through centrally regulated change in physiological set points, receives greater emphasis than it did in the first edition.

Overall, our understanding of stress mechanisms in the human has benefited from two major quantum leaps in technology. First, the advances in molecular genetics and genomics and sequencing of the human

genome (published after the first edition had appeared) have increased the rigor and precision of our understanding of the molecular neurobiology of stress. Thus, new to the second edition are a series of articles on the genetic factors that play a role in susceptibility to stress and in various components of the stress response. Secondly, functional brain imaging has enhanced our understanding of the neurobiology of stress in the human. Many of the articles in the second edition reflect the positive impact of these two advances.

Accessibility to the second edition of the Encyclopedia of Stress will be facilitated by virtue of the fact that it is published online as well as in hard copy. My profound thanks for their selfless work go to our team of distinguished authors and to my friends and colleagues on the Editorial Board. Production of the Encyclopedia would not have been possible without our colleagues at Elsevier, and in particular Bob Donaldson and Hilary Rowe whose dedication, commitment and excellent work I am pleased to acknowledge.

Note on Terminology of Corticotropin Releasing Factor/Hormone and the Catecholamines

The central nervous regulation of the anterior pituitary gland is mediated by substances, mainly peptides, which are synthesized in the hypothalamus and transported to the gland by the hypophysial portal vessels. Because these compounds are transported by the blood, the term "hormone" gained acceptance in the neuroendocrine literature. The major hypothalamic peptide involved in the stress response is the

41-amino acid corticotropin releasing factor (CRF). The Endocrine Society (USA), following convention, adopted the term corticotropin releasing hormone (CRH). However, this nomenclature has been challenged. Hauger et al. (*Pharmacol Rev* 55: 21–26, 2003), in liaison with the International Union of Pharmacology Committee on Receptor Nomenclature and Drug Classification, argued that the CRF's function extends well beyond the biology of a hormone, and that therefore it should be termed corticotropin releasing factor (CRF) rather than hormone. Since the terminology of CRF versus CRH has yet to be resolved, the two terms and abbreviations are here used interchangeably, depending on author preference.

Adrenaline and *noradrenaline* are catecholamines that play a pivotal role in the stress response. These

terms are synonymous with *epinephrine* and *norepinephrine*, respectively. Both sets of terms are used interchangeably in the endocrine, neuroendocrine and stress literature, and this principle has been adopted for the Encyclopedia. Style has depended on author preference, but wherever possible within-article consistency has been ensured.

FOREWORD

This is the second edition of the *Encyclopedia of Stress*, the three heavy volumes that first appeared in 2000 under the overall editorial guidance of George Fink. From its original coining in reference to rather unusual and unpleasant situations, the word *stress* is now quasi synonymous with *life*, i.e. modern life! This second edition of the *Encyclopedia of Stress* presents several hundreds of articles written by experts in that particular field, especially for this series, discussing, clarifying, explaining to the average-reader as well as to anyone more educated in one field or another, the extraordinary involvement of stress and our normal or abnormal reactions to it, both in our physical body and its accompanying mind. The table of contents is truly amazing, from the stress of being born to the stress of dying and so many circumstances in between, with clear presentations of the pertinent, current knowledge about them. This is truly an encyclopedia where, surely, you will find some explanation and answer to your own stresses (and those of others).

Stress-Eating
Stress-Eating and Obesity
Mechanism of Stress-Eating

Glossary

<i>Hypothalamic-pituitary-adrenal axis</i>	The hormonostatic endocrine axis that regulates cortisol production and secretion.
<i>Leptin</i>	An adipocyte-produced hormone that is involved in the regulation of satiety and energy expenditure.

The current understanding of the systems of the body and brain related to the control of energy intake, energy balance, and body weight has increased significantly since 2001. In the periphery, a variety of substances are believed to be involved in integrating physiological and behavioral systems directed towards energy homeostasis. The hormones insulin, leptin (secreted by adipocytes), and ghrelin (mainly secreted by the stomach) link the control of peripheral energy metabolism to the central nervous system (CNS) feeding behavior integrating unit by modulating short-term signals that determine meal initiation and termination as well as energy balance. The adrenal glucocorticoids (cortisol) predominantly influence the ingestion and metabolism of fat and carbohydrates. In addition to these hormones, the process of integrating metabolic information from the periphery in the CNS requires specialized functions of multiple brain areas. These include the lower brainstem, which integrates neural information between peripheral autonomic-endocrine organs and forebrain structures,

the hypothalamus, which is closely linked to circulating metabolites and hormones, and the forebrain structures, such as the nucleus accumbens and amygdala, which integrate incoming information with various cognitive aspects of food.

The role of the hypothalamus in the process of relating hormones and metabolism to eating behavior has received considerable attention. A number of neuroendocrine systems have been identified in this structure and are believed to be involved in controlling appetite for the macronutrients, carbohydrate, fat, and protein. They also modulate metabolism and contribute ultimately to weight gain and obesity.

Stress-Eating

Many overweight people, particularly those with abdominal obesity, find that eating increases in situation of discomfort and also soothes their feelings of stress and anxiety. This phenomenon is usually called stress-eating or emotional-eating. While obese individuals may realize that in general they eat in response to stress/emotions, they are typically unable in the moment to stop themselves from eating. As will be discussed below, this type of stress-eating might be due to disruptions of central regulatory systems involved in the control of energy intake. In obese binge eaters, stress-eating occurs, and it is up to 100% specifically triggered by stress and negative moods (e.g., depression, anger, anxiety, etc.).

Stress-Eating and Obesity

It is not clear if stress-eating is secondary to being obese or vice versa, stress causing overeating, resulting in obesity. It is, however, clear that obese subjects have more body image distortion and distress about their weight than normal-weight subjects. Indeed, in our society being obese is so stigmatized that few individuals who are obese are able to feel good about their size. Negative body image and feelings of stress and anxiety about being obese may thus

serve as a trigger for stress-eating. In addition, stress and anxiety about being obese may work indirectly, increasing negative emotions such as depression and thus rendering the individual more susceptible to eating in response to stress. However, no studies have been reported indicating that obese subjects overeat by stress mechanisms leading to a maintained or escalated obese state.

Our knowledge of human obesity has progressed beyond the simple generalization that obesity is fully explained by inappropriate eating. Still, in more than 80% of the cross-sectional studies linking intake data to degree of obesity, dietary fat intake was associated with obesity. It is, however, important to recognize that human obesity is not a single entity, and subgroups are clearly more or less afflicted by stress. Realizing this distinction, it may be possible to examine how stress may be directly associated with an increased energy intake, and eventually with obesity.

Obesity with an increased number of adipocytes (i.e., hypercellular obesity) typically begins in early or middle childhood. In contrast, obesity with enlarged adipocytes (i.e., hypertrophic obesity) tends to correlate with truncal fat distribution, which in turn is an important predictor of the health hazards of obesity. Certainly, differences in clinical symptomatology favor a separation of obesity into two broad categories: visceral and nonvisceral obesity. These two forms seem to have different associations to stress. Central, visceral obesity is often associated with psychosocial and socioeconomic handicaps and excess use of alcohol and tobacco, as well as traits of depression and anxiety. Psychosocial stressors might induce eating as comfort food that may directly result in reduction of the negative effects of the chronic stressor in the nucleus accumbens. In addition, socioeconomic difficulties may make it hard to purchase nutritionally healthy food.

Mechanism of Stress-Eating

The expression of appetite is underpinned by a complex set of peripherally generated signals. Key hormonal appetite factors include insulin, cortisol, and leptin. Leptin is a protein that is synthesized exclusively in adipose tissue and moderates the drive to consume food. Within the neural circuitry numerous neuropeptides, both orexogenic (e.g., neuropeptide Y and melanocortin), and anorexigenic (e.g., pro-opiomelanocortin and corticotropin-releasing hormone) have been identified which stimulate and inhibit food intake.

Resistance to the appetite-suppressing effects of leptin is associated with common forms of obesity. Is

it possible that stress factors associated with central, visceral obesity might be interfering with the leptin system? The human body holds many effector systems including the hypothalamic-pituitary-adrenal (HPA) axis for maintaining homeostasis. The secretory end product of the HPA axis, cortisol, is kept within an optimal range through the feedback action of cortisol interacting with neural control mechanisms. Distressing events or situations evokes prominent HPA system activation, and after long-term exposure, the HPA axis will eventually become dis-habituated, resulting in a disruption of central regulatory systems. Together with insulin, the cortisol stimulate drive for and ingestion of comfort foods that may directly result in reduction of the negative effects of the chronic stressor in the nucleus accumbens, through stimulation of the anterior, more pleasure-associated part of this cell group, thus reducing the weight of the stress-stimulated posterior, more defensive part. Studies in rats have indicated that cortisol is directly involved in the sensitivity of the leptin regulation of satiety. When rats are adrenalectomized, their leptin sensitivity becomes high and feeding is inhibited. When corticosterone is replaced in a dose-dependent manner, food intake and body weight follow in parallel, and with excess corticosterone, obesity due to overeating appears. Furthermore, most animal models of obesity have enlarged adrenals and overproduction of glucocorticoids. Upon adrenalectomy, the somatic feature of obesity disappears. In normal-weight subjects, cortisol induces a dose-dependent increase in plasma leptin concentrations. In obese humans, food intake is clearly elevated after glucocorticoid administration in spite of increased levels of circulating leptin, indicating the presence of leptin resistance. Taken together it seems reasonable to assume that stress-eating is primarily caused by interference of stress-related cortisol secretion, with the normal signaling of satiety by the leptin system. The resulting deficient satiety signal causes overeating and finally the appearance of overweight and obesity.

Introduction

Clinical Characteristics of OCD

Biological Characteristics of OCD

Brain Circuit Theories of OCD

Neuropsychological Testing in OCD

Neuroimaging Studies in OCD

Conclusions

Glossary

<i>Anti-depressants</i>	Drugs that are used in the treatment of depression and other psychiatric disorders, including obsessive–compulsive disorder (OCD).
<i>Basal ganglia</i>	Groups of neurons deep in the brain that serve as integrative way stations for brain circuits.
<i>Cerebral cortex</i>	The outer layer of the brain, composed mainly of nerve cells (neurons).
<i>Compulsions</i>	Repetitive behaviors or mental acts that reduce anxiety or distress.
<i>Neuro-transmitters</i>	Chemicals that carry messages from one nerve cell to another.
<i>Obsessions</i>	Intrusive and inappropriate recurrent and persistent thoughts.

Introduction

Psychiatric disorders are considered functional when there is no clearly understood central nervous system (CNS) pathophysiology underlying them. Thus, schizophrenia, the major affective illnesses, and anxiety disorders have been and are still considered functional psychiatric illnesses. This is an evolving nomenclature, however – as our knowledge about the pathophysiology of the brain in these disorders increases, the adjective functional conveys less and less meaning.

The brain substrates of the major psychiatric disorders are being examined in several ways. Complex genetic underpinnings are slowly being defined. Structural and functional imaging studies of the brain are providing some anatomical localization, limited by the resolution of the imaging techniques and the particular methodology of each study. Specific classes of drugs are known to be therapeutic for specific disorders, but the balance among chemical systems in the brain makes inferences about disturbance of a specific system in a particular psychiatric disorder difficult. Furthermore, no drug is curative of any psychiatric disorder. Obsessive–compulsive disorder (OCD) is one of the functional psychiatric illnesses that is giving way to an understanding of its pathophysiology in the brain. Stress can play a major role in the severity of OCD, and the illness itself can be very stressful to afflicted persons.

Clinical Characteristics of OCD

OCD is classified among the anxiety disorders. Its hallmarks are recurrent obsessions and/or compulsions severe enough to be time consuming (more than 1 h/day) or to interfere with occupational or social functioning. At some point, the individual must

recognize that these symptoms are excessive or unreasonable (this does not apply to children), and, if another major psychiatric disorder is present, the content of the obsessions or compulsions must be unrelated to it. Finally, the OCD must not be a direct result of a drug or an underlying medical condition.

Obsessions are recurrent and persistent thoughts, impulses, or mental images that are experienced as intrusive and inappropriate, that cause marked anxiety and distress, and that are not simply excessive worries about real-life problems. The individual recognizes that the mental intrusions are a product of his or her own mind (this distinguishes them from psychotic symptoms such as thought insertion) and attempts to neutralize them with other thoughts or actions (for example, compulsive rituals). The content of obsessions is most often violent (for example, the murder of one's child), sexual, contaminative (for example, touching unclean objects), or doubting (for example, worrying repeatedly about having performed a particular act).

Compulsions are repetitive behaviors or mental acts engaged in to reduce anxiety or distress. Common compulsive behaviors are hand washing, ordering of objects, and repetitive checking (for example, a locked door); common mental acts are repetitive counting, praying, and saying words silently. The frequency and severity of these obsessions and compulsions as necessary for a diagnosis are a minimum for these activities; not infrequently, many hours each day are spent in the throes of OCD, and compulsions may be physically damaging (for example, washing one's hands until the skin is raw). As mentioned, the individual knows these are alien thoughts and behaviors and is distressed by them, but is powerless to moderate them.

There appear to be different OCD symptom profiles across subjects. An analysis of scores on the Yale-Brown Obsessive-Compulsive Scale in more than 300 OCD patients showed that there were four relatively independent clusters of symptoms: obsessions and checking, symmetry and order, cleaning and washing, and hoarding. Other recognized clinical variants include obsessional slowness (for example, taking several hours to perform routine bathing, grooming, and dressing each day) and obsessional rumination, commonly with a hypochondriacal theme. The background personality of individuals with OCD tends to be rigid and perfectionistic. The end result of severe OCD can be impressively bizarre behavior: the housewife who must purchase new china whenever guests are invited; the adult son who cannot join his parents for the weekend because he spends 12 hours checking that his house has been properly locked; the hoarder

whose house is stuffed with trash and newspapers to the point that it is declared a fire hazard. At present, there are no laboratory tests that are diagnostic of OCD.

The lifetime prevalence of OCD is 2–3%; thus, it is not rare. OCD occurs equally in men and women and usually begins in early adulthood, although childhood OCD is not uncommon. It may co-occur with other psychiatric illnesses such as major depression, other anxiety disorders, and eating disorders. There is a high incidence of OCD (30–50%) in patients with Gilles de la Tourette syndrome, which consists of severe tics (sudden, involuntary muscle movements) and involuntary utterances, occasionally vulgar in nature. Tourette syndrome is quite rare, but approximately 5% of OCD patients may have some form of it, and 20–30% of OCD patients have a history of tics. Indeed, one formulation considers that an obsession is a psychic tic. OCD affects both twins more often in monozygotic (single-egg) twins than in dizygotic twins, and there is a higher incidence of OCD in first-degree relatives (parents, siblings, and children) of both OCD and Tourette syndrome patients than in the general population. OCD patients in stressful life situations often have a worsening of their symptoms, for example, more frequent intrusive obsessional thoughts or more frequent compulsive behaviors such as repetitive hand washing.

Biological Characteristics of OCD

Neurotransmitters (for example, serotonin, norepinephrine, and dopamine) are chemicals in the brain that are released by neurons and carry a chemical message across a short space (synapse) to activate receptors on downstream neurons. An interesting treatment finding is that OCD responds best to drugs that are serotonin uptake inhibitors (SUIs) in the brain. These drugs (for example, clomipramine, fluoxetine, paroxetine, sertraline, and fluvoxamine), block the serotonin transporter, which recycles the neurotransmitter serotonin from the synapse back into the nerve cell that released it. By blocking transporter uptake, these drugs increase synaptic serotonin concentrations, at least in the short term. This implies that reduced serotonin neurotransmission may be a neurochemical basis for OCD, but clear evidence of this, by measurement of serotonin or its metabolites, transport mechanisms, or receptors, has not yet been forthcoming.

Complicating this perspective is recent evidence that chronic treatment with an SUI completely blocks the rise of extracellular brain serotonin that occurs in response to stress. Serotonin is mainly an

inhibitory neurotransmitter in the brain, especially in areas that are implicated in OCD, such as orbital prefrontal cortex and hippocampus. In these sites, serotonin reduces the firing of cortical pyramidal cells that are essential components of the cortico-striato-thalamo-cortical circuits now implicated in OCD and major depression. SUIs are most often used as antidepressants, and it is interesting that OCD and major depression, two illnesses with different symptom patterns (although occurring together in some patients), respond to treatment with the same drugs. The common factor is now considered to be that these disorders have a similar neuropathology that is expressed in functionally segregated neuronal circuits in the brain. Relief of OCD symptoms by SUIs is not complete (about 35% on average), and only about 50% of patients respond, suggesting that more than one brain neurotransmitter system may be involved. The addition of antipsychotic drugs (for example, haloperidol) that block dopamine receptors on neurons, thereby reducing dopamine neurotransmission, can be effective, certainly when there is a tic disorder associated with the OCD, and perhaps in cases refractory to SUI treatment. Other drugs useful in selected cases as adjuncts to treatment with SUIs are lithium (used most commonly to treat manic-depressive illness) and fenfluramine, a direct stimulator of serotonin receptors. Interestingly, dextroamphetamine, a dopamine and norepinephrine neurotransmission-potentiating drug, can reduce OCD symptoms in some patients.

Another aspect of OCD that supports an underlying brain abnormality is the presence of OCD-like disorders in other mammalian species, including sub-human primates, dogs, cats, horses, pigs, cows, sheep, bears, and parrots. Compulsive behaviors in these species include repetitive grooming to the point of skin damage; hair and feather pulling; tail chasing, pacing, whirling, bouncing, and somersaulting; sucking, bar biting, and lip flapping; compulsive sexual behaviors; aggression; checking; and territorial marking. Some equine and canine compulsive behaviors are familial and breed-specific, providing support for genetic factors in these conditions.

It cannot be determined which of these behaviors animals engage in to reduce anxiety or distress vs. which are distressing to the animal, but the animal is powerless to control them, the latter being a necessary criterion for the diagnosis of OCD in humans, as indicated previously. Some behaviors, such as pacing, whirling, and compulsive sexual activity, may be engaged in because a captive animal is deprived of necessary physical exercise and environmental stimulation, and these behaviors provide some degree of

pleasure and relief from boredom. Nevertheless, some compulsive behaviors are pathological, such as acral lick in dogs, resulting in dermatitis, and avian compulsive feather picking. Several of these animal behaviors have been treated successfully with SUIs as well as with dopamine-blocking drugs.

The pharmacology of drugs useful in treating OCD points to which brain areas might be involved. Both the cerebral cortex of the frontal lobes (frontal cortex), which receives prominent serotonin connections from brain stem nuclei, and the basal ganglia, which receive dopamine connections from the substantia nigra, have been considered in OCD pathology. However, it should be noted that psychological treatments such as behavior therapy also can have a significant therapeutic effect, and brain imaging studies have shown that behavior therapy can induce changes in brain metabolism in OCD similar to those induced by drug therapy. Whether psychological therapy induces changes in neurotransmitter activity similar to those induced by pharmacotherapy is as yet unknown. In some instances of severe, incapacitating OCD that was unresponsive to all other treatments, stereotaxic cingulotomy (surgery that interrupts connections between the thalamus and the prefrontal cortex) has been effective. A significant minority of such patients experience gratifying clinical remission, but a partial response is equally common. Some 30–50% of patients, however, have little improvement from surgery.

Brain Circuit Theories of OCD

Brain circuit theories of OCD represent variations on the postulated involvement of certain areas of the frontal parts of the brain (frontal lobes) and their functional connections with deeper parts of the brain – the basal ganglia, thalamus, and other structures, including hippocampus and amygdala. There also are connections from these structures back to the cortex itself. In a general sense, the frontal lobes of the brain mediate executive functions, that is, an individual's decision-making and behavioral actions based on detailed evaluation of environmental demands, along with an appreciation of their historical context and a coordinated affective/emotional component. Particular areas of the frontal cortex mediate executive behavior, social behavior, and motivation.

The underlying theme of the brain circuit theories of OCD is that the lower, or orbital, frontal cortex is a generator of afferent impulses to the caudate nucleus, which is a part of the basal ganglia, and the caudate in turn serves as a filter or gating area. The caudate nucleus is considered to normally suppress extraneous thoughts, sensations, and actions, with little need

for control by the frontal cortex. Some investigators have hypothesized a primary defect in caudate function in OCD, which leads to an increased requirement for the frontal cortex to suppress and emotionally neutralize intrusive neuronal activity. Other investigators have viewed overactivity of the orbital frontal-thalamic circuit as the cause of compulsions in OCD, since compulsions represent unmodulated behavioral drive. The functional result is that the caudate nucleus cannot reasonably filter all the neuronal impulses sent to it from frontal cortical areas; some inappropriate or otherwise innocuous stimuli therefore are passed on to other structures, where they acquire excessive emotional meaning that results in inappropriate thoughts and actions.

Electroencephalographic (brain wave) studies of OCD subjects undergoing cognitive neuropsychological testing also support involvement of the frontal lobes, and functional neuroimaging studies suggest increased blood flow and metabolic overactivity of the orbital frontal cortex. Imaging studies of the caudate nucleus are less consistent in their findings. Thus, it is not possible at present to determine from imaging studies where in the frontal cortical/caudate nucleus/thalamus/frontal cortical circuit the primary defect resides. Structural lesions (for example, strokes and tumors) of both the frontal cortex and the basal ganglia have been associated with obsessions and stereotyped behaviors resembling compulsions. And, as mentioned, drug treatments of OCD do not particularly clarify the matter, since alteration of cortical serotonergic systems with SUIs often results in only partial relief of symptoms, and dopamine-enhancing drugs, which act on caudate nucleus dopamine systems, have some role in the management of OCD symptoms, especially when there is associated tic disorder.

Current theories emphasize hyperactivation of the lateral orbitofrontal loop in OCD, with overactivity of the orbital frontal cortex, the anterior cingulate cortex (ACC), and the caudate nucleus. As indicated previously, these brain structures also have been implicated in major depression and anxiety disorders. The ACC has been further implicated in OCD through correlative functional magnetic resonance imaging (MRI) studies of ACC activity and error checking. Compared to normal control subjects, patients with OCD have excessive error-related activation of the rostral ACC, which is correlated with the severity of OCD symptoms. One of the primary executive functions of the ACC is error detection or mismatch recognition; dysfunction in this brain region might well be associated with the inability of OCD patients to achieve cognitive closure. Failure to achieve cognitive closure is precisely what they demonstrate in their inability to terminate rituals and obsessions

despite intellectual awareness that these behaviors are not justified. For the OCD patient, it is never okay: there is always the possibility that he or she has failed to rule out some contingency. This cognitive style is also apparent in formal testing of, for example, deductive and inductive reasoning: Patients with OCD have no problem with deductive reasoning, but they are significantly impaired on inductive reasoning tasks.

Neuropsychological Testing in OCD

Neuropsychological tests can tap some of the components of frontal lobe function, but it is difficult to implicate the involvement of a particular area of the frontal lobes in OCD from impaired performance on a specific neuropsychological test. Studies indicate deficits in OCD patients' ability to shift task set. This is consistent with theories of disrupted response feedback, in which repeated compulsive acts are required to determine their adequacy. An inherent need for high accuracy in a given individual may aggravate the tendency to lose response feedback, setting up the repetitive behavioral pattern.

Another issue is whether neuropsychological deficits or changes in brain metabolic activity appears first. Altered metabolic activity may result in the behavioral and neuropsychological test changes found in OCD, but it also may be true that the anxiety and need for absolute mastery caused by the illness itself underlie the increased cerebral metabolic activity noted on electroencephalogram (EEG) and functional neuroimaging studies.

Neuroimaging Studies in OCD

With the advent of neuroimaging techniques, it now is possible to probe the structure and function of the living human brain. Brain structure can be viewed with x-ray computed tomography (CT) and MRI. Nuclear medicine techniques such as single-photon and positron-emission computed tomography (SPECT and PET) allow the visualization and quantitation of regional cerebral blood flow, glucose metabolic rate, and neurotransmitter receptor occupancy, which are indirect probes of regional neuronal function. SPECT and PET use radiolabeled compounds as tracers; as these compounds decay, high-energy photons are emitted that are counted by external detectors. The distribution of the tracer molecules is computed, and cross-sectional images of the brain are created in which image brightness is proportional to the underlying physiological process being measured.

Studies of brain structure with CT and MRI in OCD patients have not demonstrated consistent

abnormalities. Most of these studies, however, focused on the caudate nucleus or lateral cerebral ventricles; less attention has been paid to the frontal lobes. Taken together, the findings suggest that structural abnormalities may be more associated with subtle neurological deficits accompanying OCD in some patients than with the disorder itself.

In contrast to the contradictory data from structural imaging studies, a consistent finding in SPECT and PET functional neuroimaging studies of OCD has been increased frontal cortical blood flow and glucose metabolism (hyperfrontality), although the precise cortical location has varied. The hyperfrontality does not seem to be a reflection of heightened anxiety in OCD patients. On the other hand, a relationship may exist between OCD hyperfrontality and serotonin neurotransmitter dysfunction. SUIs not only reduce OCD symptoms, but also alleviate the hyperfrontality, as shown by SPECT and PET.

A tendency toward lateralized right frontal hyperactivity in OCD also has been noted. Right frontal hypermetabolism in OCD is consistent with theories of frontal emotional lateralization. The right frontal cortex is considered to play a greater role in perception of and reaction to negative primary emotions and stimuli, whereas the left frontal cortex may be more active in response to positive stimuli and positive social emotions. The inability of OCD patients to suppress negative primary emotions and thoughts occurs along with their right frontal hyperactivity. A similar formulation of predominantly right prefrontal activity has been advanced for major depression. Suppression of right hemisphere cerebral activity, either with the Wada test (transient suppression of a cerebral hemisphere by barbiturate injection into the same-sided carotid artery) or as a result of lesions, is associated with decreased apprehension, euphoric mood, and minimization of negative emotions, while left hemisphere suppression produces feelings of depression, guilt, and worries about the future. With regard to basal ganglia function, neither structural nor functional neuroimaging studies strongly substantiate the hypothesis of a caudate abnormality in OCD. They do not rule out this possibility, but rather indicate that whatever abnormality might exist has not been consistently seen with current functional neuroimaging technology.

Conclusions

There is considerable variation in obsessive and compulsive symptoms, ranging from normal time-limited worry, through obsessive-compulsive personality disorder, to self-consuming OCD. The criteria for OCD represent a consensus statement among mental health

professionals, based not only on the nature of the OCD symptoms but also on their frequency and interference with social and occupational functioning. OCD thus remains an arbitrarily defined syndrome, no matter how much expertise underlies the definition, so long as there are insufficient empirical data to validate its qualitative difference from obsessive-compulsive personality disorder, as well as from other major anxiety syndromes.

While animal models of OCD provide an interesting theoretical perspective, as noted earlier, this analogy also suffers from a certain nonspecificity. Repetitive behaviors such as pacing, whirling, hitting oneself, toe walking, and rocking, as well as increased anxiety, also are common symptoms of autism, a pervasive developmental disorder that begins in early childhood and persists into adult life. In autistic adults, dietary tryptophan depletion, which depletes brain serotonin, increases these repetitive behaviors, and treatment with SUIs decreases them. This suggests an involvement of brain serotonin neurotransmitter systems in autism similar to that in OCD.

It is interesting to speculate on the opposite of OCD, that is, excessive neglect in conducting one's activities of daily living. A large segment of society fails to adequately check their surroundings and to protect themselves from even known threats. Preventable accidents are a leading cause of mortality and morbidity, and epidemics of avoidable diseases such as AIDS are only too well known. This can be considered inappropriate denial of dangerous situations that have the potential to cause real harm to the individual. However, we approach inappropriate denial and risk taking only from a cognitive, educational standpoint, for example, trying to convince persons at risk to just say no. Perhaps our relative failure to make headway with such an approach suggests that we should take a fresh, psychobiological look at this aspect of behavior. For example, how is compulsive risk taking psychobiologically similar to or different from compulsive checking and hand washing? Psychologically they could be viewed as opposite ends of a spectrum, the former representing pathological self-neglect and the latter pathological self-protection. These and other issues remain the exciting areas of future research into OCD.

Effects on Survivors
Impact on Children
Emergency Personnel and Disaster Mental Health

Glossary

<i>Access victims</i>	Individuals who offered support and human assistance to survivors and families of victims, such as mental health professionals, nurses, and clergy.
<i>Direct-contact victims</i>	Emergency and rescue workers who searched the rubble for survivors and dead bodies, in addition to morgue personnel.
<i>Direct-impact victims</i>	Survivors who witnessed the bombing, death, and maiming of immediate victims firsthand.

<i>Disaster mental health</i>	A competency-based intervention model, based on disaster-related psychopathology, that addresses a community's mental health needs.
<i>Intraself risk factors</i>	A victim's idiosyncratic perception of the meaning and appraisal of a catastrophe and any premorbid factors that impact postdisaster reactions.
<i>Mass-casualty event</i>	The multidimensional stressors that may result in differential patterns of posttraumatic reactions, both short-term and long-term.
<i>Self-efficacy adaptational coping</i>	Survivors' struggles to maintain psychosomatic and social equilibrium.
<i>Socioenvironmental risk factors</i>	The degree of ecological and interpersonal destruction and intensity of exposure to morbidity.

Site of the Bombing

The bombing of the Alfred P. Murrah federal office building in Oklahoma City, Oklahoma, on April 19, 1995, remains the most devastating domestic terrorist act on U.S. soil. This tragic event impacted a close-knit community in America's heartland and tore at the fabric of our national sense of security. The bomb blast had a devastating impact; 168 lives were lost and nearly 1000 people were injured. Sadly, 19 children were killed and 57 were injured, some quite seriously. A majority (60%) of the fatalities were government employees. Because the event occurred in the morning, thousands of commuters were in the downtown area, in close proximity of the blast, heard the shattering explosion, and witnessed the calamity unfold. The rescue response was immediate, with hundreds of emergency workers, medical personnel, and law enforcement officials attending to the scene. During the first 48 h, the city's hospitals were overwhelmed with the critically wounded and exasperated family members while the bombing scene was amass with rescue teams in search of the survivors and victims. In a matter of minutes, Oklahoma City experienced a calamity of monumental proportions. Although the Oklahoma City bombing has many features in common with most disasters, the fact that the perpetrators were U.S. citizens added an additional stress factor to the readjustment of victims and the recovering community. The resolution of intense emotional concerns has had a central role in the healing process of not only the residents of Oklahoma City but also the nation as a whole. Perhaps this national consciousness is most evident in the poignant annual commemoration for all the victims of this tragedy.

Effects on Survivors

Disasters are usually classified as natural (e.g., hurricanes) or human-made (Three-Mile Island), but with the bombing in Oklahoma City, the American psyche was introduced to the ominous reality of disaster by intentional human strategy. In 1995, Parson coined the term Oklahoma City Bombing Stress Response (OKC-BSR), defined as (1) traumatic stress responses and (2) traumatically shattered meaning elements. In understanding victims' collective psychological responses and adaptation, Parson argued that ORC-BSR involves psychophysiological reactions to dissociation, anxiety symptoms, and acute stress disorder with a concomitant need to find meaning from a terrorist act. To address the overwhelming need for mental health services in the Oklahoma City area, a special program for individuals reporting psychological distress from the bombing (entitled Project Heartland) was established. Some 9000 residents received services such as crisis intervention and support groups. This program offered a model for investigating risk factors for posttraumatic stress disorder (PTSD) symptoms among the survivors of the trauma-related community stress.

Research studies on mental health symptomology and stress syndromes following the Oklahoma City bombing have been widespread in recent years. A study by Sprang, based on the premise that post-disaster reaction is a function of degree of exposure, found Oklahoma City residents reported high levels of PTSD and victimization symptomatology. Tucker and colleagues reported on 86 adults who sought assistance for stress related to the bombing 6 months after the tragedy. Reactions of nervousness to how others reacted at the time of the bombing accounted for approximately one-third of the variance in post-traumatic stress scores. These findings suggest that people who experience high anxiety during a traumatic event are subject to prolonged stress reactions over time. Pfefferbaum and colleagues reported in a series of studies on the long-term psychopathology and PTSD symptoms evident in both the survivors and the local population after the bombing. Survivors ($n = 37$) in the direct path of the explosion were assessed 17 months postdisaster. The results showed that 31% of the sample was designated as chronic PTSD. In another survivor sample ($n = 182$), 45% was diagnosed with postdisaster psychiatric disorders and 45% exhibited PTSD symptoms, particularly intrusive memories and hyperarousal, 6 months after the bombing. Furthermore, Pfefferbaum and colleagues, in a group of 84 individuals from the Oklahoma City community seeking support and mental health services, found a strong association between

PTSD and substance use behaviors such as smoking and alcohol intake. Such coping mechanisms have been found to exacerbate functional impairment in trauma/disaster victims. These studies on the long-term effects of the bombing confirm not only the immediacy of PTSD onset but also lingering stress response syndromes in populations with proximity to the disaster impact area. This calls for early intervention with long-term treatment options.

Because victims of a disaster may have had previous trauma, PTSD, or premorbid psychiatric conditions, they may be vulnerable to reacting pathologically to subsequent stressful events. In this regard, Moyers reported on the exacerbation of PTSD symptoms following the Oklahoma City bombing in veterans who were attending support groups.

Impact on Children

In recent years, the effects of major disasters on the mental health and emotional functioning of children has become a specialized area of research endeavor. Children are a particularly vulnerable group with the added stress of adapting to developmental milestones and dealing with emotional turmoil. In a sample of over 3000 middle school and high school students in the Oklahoma City school system, researchers found that children who knew someone who was killed by the blast (vicarious exposure) reported higher PTSD severity than did children who were not highly exposed to the traumatic event. Bereaved youths were more likely than nonbereaved peers to experience symptoms of anxiety and fear, changes in both school and home environments, and PTSD-type symptoms. Interestingly, girls reported significantly higher PTSD severity scores than boys. In addition, students who viewed extensive television coverage of the bombing were most negatively affected. These findings support prior research on the functional role that the defense mechanism of denial plays in the adaptation of children to the onerous impact of psychic trauma and disasters.

Emergency Personnel and Disaster Mental Health

A review of the literature on trauma provides conflicting evidence on the prevalence of stress reactions in emergency services personnel and rescue workers in the aftermath of disasters. Studies of firefighters and rescue personnel who responded to the bombing reported an unexpectedly low incidence rate (13%) for PTSD, even 3 years postdisaster. Body

handlers were found to have negligible symptoms of depression or PTSD, and their overall mental health status improved over time. The resilience factors that aided in adaptation for these emergency personnel were identified as professional hardiness, job experience, and postdisaster debriefing.

Conversely, mental health workers in Oklahoma City reported chronic stress due to the increased workload for an extensive time period after the bombing. In fact, disaster mental health personnel were most prone to compassion fatigue and burnout. These findings illustrate the critical importance of professional education and psychosocial support initiatives. The implications for occupational stress, mental health, and organizational efficacy for emergency service workers cannot be ignored. Future research must focus on competency in conducting both disaster planning and postdisaster intervention.

Overview

Neuroendocrine Responses

Opioids and Stressor Processing

Opioids, Stress, and Reproduction

Conclusion

Glossary

β-Endorphin

A 31-amino-acid endogenous opioid peptide that acts mainly on δ - and μ -opioid receptors, synthesized from the proopiomelanocortin (POMC) gene. Cells expressing POMC are found in the arcuate nucleus of the hypothalamus, the corticotroph cells of the anterior pituitary, and the cells of the intermediate pituitary. Nerve fibers containing β -endorphin innervate the hypothalamus and project to other brain regions.

Agonist

Drug or exogenous or endogenous substance that binds to a receptor in a cell to induce a response.

Analgesia

The relief from pain; it may be local, spinal cord-mediated, or central.

Antagonist

A drug or endogenous substance that binds to a receptor in a cell-displacing bound agonist to prevent or reverse the effect of the endogenous ligand or agonist.

Dependence

The result of chronic exposure to an opiate drug that causes withdrawal signs to occur when the opiate exposure is interrupted; also called addiction.

Dynorphins

Endogenous opioid peptides that are 8 or 17 amino acids long and act mainly on κ -opioid receptors but also partly on δ - and μ -opioid receptors; synthesized from the preprodynorphin gene (also known as preproenkephalin B).

Endomorphins

Endogenous opioid peptides (discovered in 1997) that are 4 amino acids long and act selectively on the μ -opioid receptor; the gene or precursor is not known.

Enkephalins

Endogenous opioid peptides that are five amino acids long (Met⁵ and Leu⁵ enkephalins) and act mainly on δ - but also on κ - and μ -opioid receptors; synthesized from the preproenkephalin A gene. They are present in neurons widely distributed in brain, spinal cord, and adrenal medulla.

Euphoria

The conscious sensation of pleasure or feeling of well-being.

<i>Limbic system</i>	Part of the brain comprising the amygdala, bed nucleus of the stria terminalis, hippocampus, septum, and nucleus accumbens that is concerned with memory, emotionality, and the processing of stressors.
<i>Morphine</i>	An opiate alkaloid produced by the opium poppy that acts in the brain and peripherally to cause analgesia, euphoria, and reduced alarm; it is a relatively selective μ -opioid receptor agonist. Opium and heroin, a modified form of morphine, are widely abused for their pleasurable effects, but they induce tolerance and dependence (addiction).
<i>Naloxone</i>	A general opioid receptor antagonist with greatest activity at μ -opioid receptors; it enters the brain from the circulation readily and reverses opioid agonist effects rapidly. It precipitates withdrawal symptoms in opiate addiction.
<i>Nociceptin</i>	A peptide related to dynorphin that binds to ORL1 (OP4) receptors, which are related to κ -opioid receptors. It lacks the classic action of opioids, is not antagonized by naloxone, and has central pronociceptive properties; also called orphanin FQ.
<i>Nociception</i>	Processes involved in perceiving pain following the stimulation of nociceptive nerve endings (nociceptors).
<i>Opiate</i>	A drug derived from exogenous sources, originally the opium poppy, producing opium-like effects.
<i>Opioid</i>	A drug or endogenously produced compound (e.g., opioid peptide) that acts through opioid receptors to produce effects that are antagonized by naloxone.
<i>Opioid receptors</i>	Proteins in the cell membrane that confer sensitivity to opioids and opiates in the cells that express them; there are three, μ , δ , and κ . They have seven transmembrane domains, ligand-binding sequences projecting extracellularly, and a G-protein binding region intracellularly; a $G_{i/o}$ -protein mediates the intracellular effects.
<i>Orexigenic</i>	Being appetite stimulating; applied to an endogenous substance.
<i>Pain threshold</i>	Often defined by the time a subject takes to respond to an applied painful stimulus of set intensity (e.g., in the tail flick test, which is applying radiant heat to the tail).
<i>Plasticity</i>	Adaptation of an endogenous system so that its response to a particular stimulus or set of stimuli changes with repeated exposure or with a change in the physiological state of the individual.

Tolerance The effect of an opiate drug on receptor and postreceptor mechanisms in a cell so that the same dosage of a drug has a reduced effect and the dosage must be increased to maintain the same effects.

Overview

The soporific and analgesic properties of opium have been known to humans for thousands of years. Morphine, an alkaloid produced by the opium poppy, *Papaver orientale*, is the prototypic opioid. It and related synthetic opiates, such as heroin, have been widely used to control pain while reducing the state of alarm in those with severe injury or suffering the pain of acute myocardial infarction, advanced cancer, surgery, or childbirth. These drugs are widely abused because of their euphoric properties, but they induce tolerance and dependence. Sexual activity is reduced in opiate-dependent individuals. An overdose of morphine results in respiratory depression that can lead to death, but the potent antagonist naloxone acts rapidly to reverse the depression. Experimentally, these drugs have provided the tools to characterize opioid mechanisms. Pharmacological studies with various opiate drugs and antagonists identified three principal types of opiate receptor (μ , δ , and κ , according to their affinities for different agonists). These were found in the brain, spinal cord, posterior pituitary gland, gut, and other tissues. They are proteins, synthesized within the opioid-sensitive cells and inserted into the lipid plasma membrane so that the amino acid sequence that tightly binds the opioid ligand is exposed on the cell surface. The hypothesis that the expression of these high-affinity receptors for opiate drugs indicated the presence of endogenously produced ligands led to the discovery of the endogenous opioid peptides in the early 1970s. Three families were discovered: the enkephalins, β -endorphin, and the dynorphins. Subsequently, a peptide related to the dynorphins, nociceptin (or orphanin FQ), was discovered, but this acts on a different receptor (ORL1) that the other opioids do not act on. Naloxone is not effective at this receptor, and nociceptin lacks the classical actions of opioids. Indeed, in some paradigms it enhances pain perception. The three types of opioid receptors, although defined initially on the basis of their distinctive affinities for different opiate drugs and, in the early 1990s, by the characterization of their genes, in general do not selectively bind the different types of endogenous opioids. The enkephalins bind to μ - and δ -, β -endorphin binds to μ - and κ -, and the dynorphins bind to κ -receptors. However, opioid peptides (endomorphins 1 and 2)

selective for the μ -receptor have been identified in the brain. The enkephalins, β -endorphin, the dynorphins, and nociceptin are produced by the processing of higher-molecular-weight precursors, each translated from a distinct gene. However, each of the opioid precursor proteins contains opioid peptide sequences also present in the other two, indicating their common origin from an ancestral gene. Similarly, the opioid receptors are all members of the seven-transmembrane-domain G-protein-linked family, with considerable homology in their sequences. The G-protein binding part of the receptor is in the cytoplasmic loops. The intracellular G-protein links the receptor to the intracellular process that the opioid affects; this link may be direct (e.g., to an ion channel) or involve the inhibition of second-messenger (cAMP) generation. The G-protein is the $G_{i/o}$ type; it is inactivated by the pertussis toxin, and this is used as an experimental tool to determine whether a $G_{i/o}$ -protein is involved in a particular opioid action.

Two principal types of opioid actions on neurons have been identified: presynaptic and postsynaptic. When opioids act presynaptically on nerve terminals, they inhibit the entry of Ca^{2+} ; because such Ca^{2+} entry is essential for the release of a neurotransmitter into the synaptic cleft, opioids inhibit release, reducing the effectiveness of the synapse. If the opioid-inhibited presynaptic neuron produces an excitatory transmitter, then the postsynaptic neuron is inhibited; conversely the presynaptic opioid inhibition of an inhibitory neuron excites the postsynaptic neuron. Opioids can also act postsynaptically on the dendrites or cell bodies of neurons, inhibiting the processes that generate action potentials and, thus, indirectly inhibiting the release of the neurotransmitter from the terminals of these neurons. The mechanism of this type of opioid inhibition involves the activation of K^+ channels in the plasma membrane; the outflow of K^+ then hyperpolarizes the neuron, making it less excitable. This mechanism also contributes to opioid actions on nerve terminals. Nociceptin has similar modes of inhibiting neural activity. The actions of opioids reverse when the opioid diffuses away or is broken down by local proteases into peptides that have little affinity for the opioid receptors. The combination of an opioid receptor with an endogenous peptide leads to the internalization and activation of other intracellular regulatory mechanisms that blunt further opioid action. It seems that these mechanisms do not follow the occupancy of the μ -receptor with morphine, and this may underlie the addictive properties of morphine.

Plasticity is a feature of opioid systems. This is evident in the increased or decreased expression of

opioid receptors or opioid peptides, which may be a result of the altered activity of their genes. The expression of the preproenkephalin and preprodynorphin genes is regulated by promoter sequences responding to intracellular messengers. The pro-opiomelanocortin (POMC) gene (which encodes β -endorphin) has a glucocorticoid receptor-response element that mediates the inhibition of expression in the anterior pituitary but mediates its stimulation in β -endorphin neurons. Opioid receptor expression can change because of redistribution within a neuron or altered turnover at the plasma membrane.

The principal actions of opiate drugs on mental state and pain perception suggest that the activation of endogenous opioid mechanisms during stress moderate the processing of stressors and the responses to them. There are several lines of evidence for this. First, the opioid peptides and their receptors are found, at appropriate sites, to influence reactions to stress. Second, the actions of opioid antagonists reveal activity in endogenous mechanisms; the effects of exogenous opioids, and the consequences of absence of opioid peptides or their receptors in mutants, all point to important roles for endogenous opioids in stress. Third, the loss of responses suspected to be due to endogenous opioid action after chronic morphine treatment, which produces tolerance to opioid actions at μ -receptors, indicates a cross-tolerance to an endogenous opioid action. It is clear that endogenous opioid mechanisms are involved in modulating reactions to stress at many levels. For physically painful stimuli, endogenous opioids modulate processing in the nociceptive pathways. Opioids are present in the brain-stem nuclei concerned with stressor processing and, similarly, in the limbic system. Opioids act in parts of the brain concerned with pleasure and reward, and here they affect appetite. Opioid peptides are coexpressed in the neuroendocrine neurons that mediate hormonal stress responses, and these neurons can be targets for opioid peptides. In the periphery, endogenous opioids modify the activity of immune cells and modulate inflammatory pain by actions on nociceptive nerve terminals. Opioids impinge on the neuroendocrine neurons regulating gonadal activity.

The major sources of endogenous opioids are the anterior pituitary gland and the medullae of the adrenal glands, which can both secrete opioid peptides (β -endorphin and enkephalins, respectively) into the circulation when stimulated; the brain and spinal cord, where opioids are produced by specific neurons; and the cells of the immune system, when activated. Opioids produced by neurons (β -endorphin, enkephalins, or dynorphins) act locally in the immediate vicinity of the site of release from the terminals of

the processes of the neurons. Enkephalins and dynorphins are commonly produced in neurons also producing other transmitters, whereas β -endorphin neurons also produce other products of the POMC gene. Opioids from neurons generally inhibit the activity of other neurons or act back on the neuron terminals from which they have been released, inhibiting further the release of transmitters. The opioids (principally β -endorphin) produced by immune cells also act locally at the site of inflammation. For opioids secreted into the circulation, there is a problem about their site(s) of action. The concentrations of opioid peptides in the circulation may not reach levels sufficient to activate the receptors in distant tissues, and blood-borne opioids may not penetrate the tissues to reach cells bearing opioid receptors. In particular, the tight junctions between the lining cells of the blood capillaries in most regions of the brain (the blood-brain barrier) prevent the free diffusion of peptides into the brain. There are transport mechanisms in the choroid plexus for selectively transporting certain peptide messengers (e.g., leptin) from blood into the cerebroventricular system. However, there is little transfer of β -endorphin from the blood into cerebrospinal fluid, and it does not then permeate the brain tissue. Enkephalins produced in the brain are removed partly by being transported into the blood, which seems to preclude their being transported in the opposite direction. Dynorphins are not transported into the brain. Furthermore, in experimental animals, after the removal of the pituitary and adrenal glands, thus eliminating these sources of opioid peptides, pain control during stress can persist; this shows the importance of opioids produced within the brain or spinal cord. Thus, it is unlikely that the activity of neurons in the brain can be directly affected by opioid peptides circulating in the blood. This is not true of the opiate drugs, such as morphine, which enter the brain and have major actions on receptors and on neurons inside the blood-brain barrier, or of antagonists, particularly naloxone, which enters the brain readily and reverses the effects of an opiate drug overdose very rapidly. A modified form of naloxone (naloxone methylbromide), with an altered charge, does not cross the blood-brain barrier; this is used experimentally to distinguish the activity of opioids within the brain from the activity of those outside.

In general, the activation of endogenous opioid mechanisms by stress reduces the perception of pain; modulates autonomic (sympathetic nervous system) and neuroendocrine mechanisms that bring about metabolic adjustments to meet the stress; stimulates eating, especially of highly palatable foods during stress; and inhibits energetically costly activities that

are not essential for immediate survival, especially reproduction. This article reviews the mechanisms.

Neuroendocrine Responses

Opioids and the Hypothalamic-Pituitary-Adrenal Axis

Endogenous opioid and opioid receptor expression in the hypothalamic-pituitary-adrenal system The defining neuroendocrine outcome of stress is the release of corticotropin releasing hormone (CRH) and vasopressin from the terminals of parvocellular paraventricular nucleus (PVN) neurons in the median eminence, causing increased secretion from the anterior pituitary gland of adrenocorticotrophic hormone (ACTH), which stimulates the secretion of glucocorticoids from the adrenal cortex. Endogenous opioids are cosynthesized and/or have actions at all these locations to modulate responses to stress ([Figure 1, i, ii](#)). In the paraventricular nucleus, the parvocellular CRH neurons also synthesize enkephalins from the preproenkephalin A gene and express opioid (at least, κ -) receptors. Preproenkephalin A gene expression is rapidly stimulated in these neurons in response to stress. Endomorphins 1 and 2 have also been described in neurons and fibers in the paraventricular nucleus. There are opioid receptors in the median eminence that mediate local regulation at the level of the terminals secreting releasing factors into the hypothalamo-hypophyseal portal system. Opioids acting here could be enkephalins coreleased with CRH or secreted by the adrenal medulla or by β -endorphin from the anterior pituitary because the blood-brain barrier is deficient in this region. Corticotrophs in the anterior pituitary synthesize both ACTH and β -endorphin from the POMC gene, and they are cosecreted; however, much of the β -endorphin may be acetylated and, consequently, inactive. This changes in pregnancy (the placenta produces POMC in women). ACTH release from the corticotrophs is not directly influenced by any opioid released locally or carried in the portal blood from neuroendocrine neurons. The adrenal cortex does not produce opioid peptides in the rat, guinea pig, human, or bovine, but in the rat it does show specific receptors for β -endorphin and dynorphin in the zona fasciculata-reticularis. However, the adrenal medulla in many species (rat, mouse, human, guinea pig, horse, rabbit, and bovine) expresses preproenkephalin A and POMC-derived opioids. These appear to influence the adjacent cortex locally; enkephalins and dynorphins are generally stimulatory in the rat and endorphins are generally inhibitory to glucocorticoid secretion in both the rat and human. Adrenal

Figure 1 The distribution of opioid peptides and opioid receptors in key elements of central and peripheral structures that organize stress responses. The elements illustrated (not to scale) are (i) neuroendocrine brain and pituitary gland (sagittal section), (ii) adrenal gland, (iii) spinal cord pain pathways (transverse section), (iv) immune cells, and (v) mesolimbic reward circuit. For each element, the predominant types of opioid receptor and the type of opioid peptide (in parentheses in boldface) present or produced are indicated. Note that β -endorphin-producing neurons in the brain are located in the arcuate nucleus (with a few in the nucleus tractus solitarius) and project to many brain regions (as in (v)). Endomorphin-producing neurons are localized in the hypothalamus and nucleus tractus solitarius. Enkephalin- and dynorphin-producing neurons are more widely distributed. Other transmitters in the key central nervous system areas are indicated (in parentheses in italics). Neural pathways modulated by opioids are indicated by straight or long curved arrows; short curved arrows indicate local opioid action; dot-dash lines indicate opioids carried in blood. 5-HT, serotonin; β E, β -endorphin; δ , κ , and μ , δ -, κ -, and μ -opioid receptors; AcCh, acetylcholine; C, A δ , C- and A δ -fiber; CeA, central nucleus of amygdala; CRH, corticotropin releasing hormone; DA, dopamine; DLF, dorsolateral funiculus; DRG, dorsal root ganglion; Dyn, dynorphin; EM, endomorphin; Enk, leu-, met-, or extended enkephalin; GABA, γ -aminobutyric acid; Glu, glutamate; GnRH, gonadotropin releasing hormone; His, histamine; LC, locus coeruleus; NE, norepinephrine; NTS, nucleus tractus solitarius; OXT, oxytocin; PAG, periaqueductal gray; pPVN, parvocellular paraventricular nucleus; Raphe, raphe nucleus; sNAcc, shell of nucleus accumbens; SP, substance P; TLS, thoracolumbar sympathetic outflow; VP, vasopressin; VTA, ventral tegmentum.

corticosteroid secretion is increased after naloxone in the human independently of a change in ACTH secretion.

Endogenous opioid and opioid receptor expression in inputs to the hypothalamic-pituitary-adrenal axis Neural inputs to the hypothalamic-pituitary-adrenal (HPA) axis that contain opioids include β -endorphin nerve terminals of arcuate nucleus neurons (adjacent to the median eminence), which traverse the median eminence and innervate the hypothalamus, including the paraventricular nucleus. CRH neurons in the paraventricular nucleus are contacted by β -endorphin terminals. Thus, β -endorphin can act on both the cell bodies of CRH neurons

and their terminals in the median eminence to influence CRH and vasopressin and/or opioid release at these sites. Endomorphin 2-expressing cell bodies have been located in the hypothalamus, near the third ventricle. In addition, opioids (enkephalins and dynorphins) are synthesized in the neurons of the nucleus of the tractus solitarius (NTS) and ventral medulla in the brain stem, colocalized in noradrenergic neurons, among others; these project to the hypothalamus, including to the paraventricular nucleus and median eminence (Figure 1, i). NTS neurons coexpressing prodynorphin or proenkephalin A mRNA are activated during seizures and other stressors, increasing their expression of prodynorphin mRNA after seizures. The limbic brain regions (the

amygdala; septum; bed nucleus of stria terminalis, BNST; and hippocampus) express opioid receptors and receive opioidergic inputs. Locus coeruleus noradrenergic neurons, important in arousal and attention in response to stressors, receive stimulatory CRH and inhibitory enkephalin-containing terminals, giving the basis for the activation and then the suppression of the activity of these noradrenergic neurons with an acute stressor. After chronic morphine exposure, the effect of CRH is enhanced, and this may exemplify how opiate addiction sensitizes to stressors and how stress predisposes to opiate craving. The amygdala has μ -opioid receptors in both rat and human, and it expresses endomorphin 2 in the rat; μ -, δ -, and κ -opioids all stimulate neurons in the amygdala in the guinea pig. Naloxone prevents stress-induced changes in long-term potentiation in the hippocampus. The septum expresses μ -opioid receptors. Enkephalin-containing neurons in the BNST are contacted by noradrenergic axon terminals and are activated by stressors. Nociceptin and its receptor (ORL1) have been described in both the amygdala and the hippocampus. δ -Receptors are not found in the paraventricular nucleus, pituitary, or adrenal cortex but may weakly contribute to regulating basal HPA secretion, perhaps via distant inputs. Thus, both brain-stem and limbic system neurons involved in mediating the activation of paraventricular nucleus CRH neurons by stressors either produce opioids or can be affected by them.

Endogenous opioids and hypothalamic-pituitary-adrenal stress responses The major effects of opioids on HPA axis stress responses are in the brain. Acutely administered opioids generally act in the hypothalamus to inhibit CRH secretion and hence ACTH secretion in most species. In the sheep, pig, and human, endogenous opioids inhibit basal and stress-stimulated HPA axis activity; and in the horse, opioids are inhibitory but naloxone increases ACTH secretion without altering CRH or vasopressin release. However, in the rat, opioids are stimulatory to the HPA axis. Thus, the release of CRH is increased following the central application of an opioid peptide (e.g. β -endorphin) *in vivo* or *in vitro*, and the effect is blocked by naloxone. The activation of endogenous opioid peptide mechanisms impinging on CRH neurons during stress (including emotional and physical stressors) is indicated by a reduced ACTH response after treatment with the antagonist naloxone. However, there are conflicting reports of tonic opioid-mediated inhibition. The subtle change of a single nucleotide polymorphism (SNP) in the rhesus monkey μ -opioid receptor gene, which increases the affinity of the receptor for β -endorphin, is associated with

reduced basal cortisol secretion. Surprisingly, whereas the central administration of morphine, a μ -receptor agonist, increases corticosterone secretion in the rat, a selective endogenous μ -receptor agonist (endomorphin-1 or -2) does not. In humans, naloxone increases basal ACTH secretion in most subjects and has a greater effect in patients with depression than in patients with Cushing's disease. A naloxone test has been suggested as an aid to distinguishing these conditions, on the basis that naloxone acting in the brain will further enhance CRH release, and hence ACTH secretion, in depressed patients with hypercortisolism but not in patients with Cushing's disease. The different opioid effects on the HPA axis may be the result of different opioids acting through different types of opioid receptor, such that μ -opioids activate and κ -opioids inhibit, and at different sites, depending on the stimulus conditions. The balance of these different actions may even change the evident direction of action from stimulation to inhibition (or vice versa) and account for species differences. Such a change has been described in late pregnancy in the rat, when endogenous opioid inhibits the activation of CRH neurons in response to several stressors by inhibiting the release of norepinephrine in the paraventricular nuclei.

The opioid enhancement of HPA axis secretory responses in rats shows plasticity during chronic stress, aging, and pregnancy/parturition. Because chronic stress increases the expression of the preproenkephalin A gene in parvocellular PVN neurons, their release of enkephalins is expected to increase. Furthermore, the neurons in the parvocellular PVN that produce enkephalin and CRH continue to be activated by an acute stressor after chronic stress. This suggests an important role for the coproduced enkephalin in mediating or modulating the HPA stress response after chronic stress. The opioid regulation of stress responses seems to decline with age because naloxone has a reduced effect, both on HPA axis responses and on stress-induced analgesia. During parturition in the rat, the usual opioid enhancement of secretory responses switches to inhibition, restraining HPA axis secretion. This follows an attenuation of HPA axis stress responses in late pregnancy, partly due to a lack of endogenous opioid enhancement. However, arcuate nucleus POMC expression and hypothalamic β -endorphin content increase in pregnancy in the rat (β -endorphin concentration in the blood also increases in both rat and human during pregnancy). Furthermore, β -endorphin can reduce CRH expression in the PVN and reduce POMC expression and ACTH secretion in the pituitary after stress. Thus, although it is possible to define the importance and characteristics of opioid actions at multiple sites in

the neural networks regulating the HPA axis, the net effect on the output is not easy to predict. The experimental finding that chronic prenatal exposure to morphine can dampen the ACTH response of the offspring to stress when they become adult indicates that the baby born to an opiate-addicted mother may be programmed to respond less to stress.

In summary, endogenous opioid mechanisms are activated by stress and modify HPA axis responses to stress at several levels in the axis. The activity of these opioid mechanisms is not fixed, and this contributes to altered HPA responses to stress, for example, as a result of reproductive activity or chronic disease. β -Endorphin is secreted into the circulation when ACTH is secreted and may have distant actions through opioid receptors outside the brain.

Opioids in the Hypothalamic-Neurohypophyseal System

Oxytocin is secreted into the blood from the nerve terminals in the posterior pituitary gland of magnocellular neurons that have their cell bodies in the supraoptic nucleus and PVN in the hypothalamus. These neurons, and hence oxytocin secretion, are stimulated by emotional and physical stressors in the rat (but generally not in other species), in which vasopressin is the posterior pituitary stress hormone. Although oxytocin may act directly on the adrenal cortex to enhance basal corticosteroid secretion, its role in the periphery in coping with stress remains unclear. Oxytocin secretion is inhibited by opioids. In the rat, vasopressin is secreted into the blood (from magnocellular neurons adjacent to oxytocin cells) in response to noxious stimuli and probably mediates cardiovascular compensation as well as conserving water by its renal actions; endogenous opioids can restrain the vasopressin response. Other stressors, such as conditioned fear, inhibit vasopressin secretion, but opioids are not responsible for this.

Opioid peptides and opioid receptor expression in the hypothalamic-neurohypophyseal system Oxytocin neurons coexpress the endogenous opioids, enkephalins and dynorphins, in both the supraoptic nucleus and PVN. These opioids are costored in the nerve terminals in the posterior pituitary and are coreleased with oxytocin on stimulation, and thus they can autoregulate oxytocin secretion into the blood (Figure 1, i). Opioids originating from the nearby anterior and intermediate lobes of the pituitary are evidently not important. Endogenous opioids also come from the adjacent vasopressin neurons, which coexpress and secrete dynorphins from their nerve terminals in the posterior pituitary and from inputs

to the oxytocin neuron cell bodies from the arcuate nucleus (β -endorphin) or brain stem (enkephalins). The magnocellular cell bodies of oxytocin neurons in the supraoptic nucleus and PVN have κ - and μ -opioid receptors, but their nerve terminals in the posterior pituitary have only κ -opioid receptors; vasopressin neurons are sensitive to κ -opioids only. Although Met⁵- and Leu⁵-enkephalins are not active at κ -receptors, the extended forms Met-enkephalin-Arg⁶Phe⁷ and Met-enkephalin-Arg⁶Gly⁷Leu⁸ are; these are produced by oxytocin neurons, and like dynorphins they can inhibit stimulated oxytocin secretion from the posterior pituitary. δ -Opioid receptors are not evident in the hypothalamic-neurohypophyseal system (HNS) and δ -acting opioids are not important in its regulation. Inputs to the magnocellular supraoptic nucleus and PVN arise from other areas of the hypothalamus, the brain stem, the circumventricular organs, the BNST, and the olfactory bulb. Although most of these regions express opioid peptides and opioid receptor binding, and opioids could affect the activity of these inputs, their role in oxytocin and vasopressin responses to stress is not known.

Endogenous opioids in hypothalamic-neurohypophyseal system responses to stress Oxytocin neuron activity and secretion are inhibited by exogenous or endogenous opioids under stimulated conditions in males and females. Thus naloxone increases and κ - or μ -opioids inhibit oxytocin secretion in response to parturition, suckling, hyperosmotic stimuli, and stress (e.g., forced swim, restraint, surgery, or white noise), the major physiological conditions that increase oxytocin secretion. In the supraoptic nucleus, opioids can act directly on the oxytocin neurons, inhibiting their discharge of action potentials via κ - or μ -opioid receptors, and act presynaptically on μ -opioid receptors to inhibit the release of neurotransmitters from brain-stem inputs. However, the inhibition of oxytocin secretion by endogenous opioids is so far known to occur only at the oxytocin nerve terminals in the posterior pituitary, except in pregnancy. The mechanisms of opioid action here are similar to those on other nerve terminals. Opioid antagonists such as naloxone increase oxytocin secretion into the blood in response to stressors in the rat. Researchers believe that κ - and μ -opioid receptors are differentially involved in regulating responses to different stressors in the rat; thus, endogenous μ -opioids regulate oxytocin secretory responses to immobilization, whereas endogenous κ -opioids regulate responses to intraperitoneal hypertonic saline. The μ -opioid receptor actions are likely to be in the brain rather than the posterior pituitary, but the

sites of action of endogenous opioids during stress are unknown.

There is plasticity in the opioid regulation of the HNS. Acute hyperosmotic stress induces the secretion of oxytocin and vasopressin and upregulates proenkephalin (weakly) and prodynorphin gene expression in the supraoptic nucleus. However, chronic stress in rats more strongly upregulates preproenkephalin A gene expression in supraoptic neurons. In pregnancy, oxytocin secretory responses to stress are attenuated more strongly by endogenous opioids. A central site of opioid inhibition is likely at this time because there is a downregulation of κ -opioid receptors and a decreased sensitivity to κ -opioids in the posterior pituitary. The upregulated endogenous opioid mechanism in pregnancy involves increased proenkephalin A and μ -opioid receptor mRNA expression in the brain-stem input and, possibly, increased β -endorphin action from arcuate nucleus neurons. The upregulation of endogenous opioid inhibition of oxytocin neurons in pregnancy is driven by neuroactive steroid products of progesterone metabolism in the brain. The more powerful opioid restraint of oxytocin neurons that emerges in pregnancy acts to restrain the responses of oxytocin neurons to a range of stressors, including interleukin-1 β . This opioid-induced resistance of the oxytocin system to stressors, and especially immune signals, in pregnancy may be important in preventing premature activation of parturition. Paradoxically, stress slows parturition by decreasing oxytocin secretion in a naloxone-reversible way. Stress may still have a stimulatory effect on oxytocin secretion in parturition, but may disrupt the pulsatile pattern of secretion that is essential for parturition (see **Oxytocin**).

In the rat, vasopressin secretion from the posterior pituitary into the blood is restricted to selected stressors – for example, to electrically applied foot shock, surgical stress, and noxious stimuli but not to restraint, forced swimming, noise, and novel environment exposure. Opioids generally inhibit magnocellular vasopressin secretion via central κ -opioid receptor mechanisms in rats and humans. Partly, this reflects the autoregulatory action of dynorphin, which is evidently released by the dendrites of vasopressin neurons during periods of electrical activity (phasic bursts) and, acting through κ -opioid receptors on the neurons, eventually terminates each burst. Otherwise, the effects of endogenous opioids on stress-induced vasopressin release are dependent on the stressor. For instance, naloxone augments the vasopressin secretory response to foot shock. Endogenous opioids are not responsible for the lack of vasopressin secretion in response to stressors such as forced swimming or restraint in the rat and this does

not change in altered physiological conditions such as pregnancy.

In summary, for posterior pituitary hormone secretion, and on stimulated oxytocin secretion in particular, endogenous opioids have powerful moderating actions at several levels under stressful conditions. These actions can be seen as contributing to a successful outcome of pregnancy.

Opioids and the Adrenal Medulla

The stimulation of the sympathetic nervous outflow from the spinal cord drives the secretion of epinephrine from the adrenal medulla chromaffin cells as part of the flight-or-fight response to stress. The adrenal medulla is an important site of opioid modulation of stress responses.

Endogenous opioid and opioid receptor expression in the adrenal medulla Soon after the discovery of the endogenous opioids, it was recognized that the adrenal medulla produces abundant opioids. In particular, proenkephalin A is expressed by chromaffin cells, which produce the catecholamines, epinephrine, and norepinephrine. These are secreted into blood when chromaffin cells are excited through nicotinic receptors by their cholinergic preganglionic sympathetic innervation from the spinal cord, that is, in acute stress (**Figure 1, ii**). Thus, the phenylethanolamine *N*-methyltransferase (the enzyme synthesizing epinephrine) and preproenkephalin A genes are expressed in the same cells. The preproenkephalin A protein is processed by a serine protease to yield Met⁵- and Leu⁵-enkephalins but also the extended peptides Met-enkephalin-Arg⁶Phe⁷ and Met-enkephalin-Arg⁶-Gly⁷Leu⁸. Enkephalins and epinephrine are packaged in the same secretory vesicles, and the stimulation of the chromaffin cells with acetylcholine or nicotine increases the secretion of both epinephrine and enkephalins into the blood, with the possibility of distant opioid actions. Such excitation increases the expression of the preproenkephalin A gene and the subsequent synthesis of enkephalins, so the secretion of opioid can be sustained during continual stimulation. Pro-inflammatory cytokines stimulate or enhance the release of enkephalins from the chromaffin cells, indicating that production is increased with infection. The capacity of adrenal chromaffin cells to produce opioids is demonstrated by the analgesia caused by fragments of adrenal medulla implanted adjacent to the dorsal horns of the spinal cord or in the periaqueductal gray (PAG) in experimental models of chronic pain. POMC is also expressed. Only a few adrenal medullary cells express the prodynorphin gene, except when these cells become tumorous (pheochromocytoma), when dynorphin is

abundantly produced. Nociceptin is also produced. There are opioid receptors in the adrenal medulla, κ -opioid receptors are present on the nerve fiber tracts and in the epinephrine-producing chromaffin cells, δ -opioid receptors are present on the norepinephrine-producing cells, and μ -opioid receptors are present at a low level. The adrenal medulla thus provides a microcosm to investigate the pre- and post-synaptic actions of opioids on neurons.

Endogenous opioids and adrenal medulla stress responses

A presynaptic action of opioids has been shown with *in vivo* microdialysis of the adrenal medulla, revealing the inhibition by μ - and δ -opioid agonists of stimulated acetylcholine release. The cholinergic nerve terminals probably release enkephalin when stimulated, causing autoinhibition at these terminals as well as inhibition by enkephalin released from the chromaffin cells (Figure 1, ii). Exogenous opioids inhibit catecholamine (norepinephrine) release from chromaffin cells induced by splanchnic nerve stimulation or by nicotine, but this is not reversed by naloxone, and indeed opioid antagonists have a similar effect, so classic opioid receptors do not seem to mediate this action on the strong stimulation of the chromaffin cells. These actions of both opioid agonists and antagonists involve the inhibition of nicotine-stimulated Ca^{2+} entry, essential for exocytosis of the contents of the secretory granules. However, other studies at the level of individual cells show clear stereospecific, opioid receptor-mediated actions. Opioids released by chromaffin cells act through the δ - or μ -opioid receptors on these cells to inhibit secretion by reducing the opening of voltage-activated non-L type (N or P/Q) Ca^{2+} channels through a pertussis-toxin-sensitive G-protein but also by inhibiting L-type channels, thus reducing the Ca^{2+} signal for exocytosis. The effects on N or P/Q channels are voltage dependent, that is, are evident when the cells are activated by depolarization. These effects last for several seconds after the secretion of enkephalin. In addition, μ -opioids activate large conductance Ca^{2+} -dependent K^+ channels (BK), which reduce Ca^{2+} influx by decreasing the action potential duration when the chromaffin cells are excited by sympathetic nerve stimulation. In this case, there is a tight coupling between the μ -opioid receptor and channel, not involving the G-protein or phosphorylation. Together, these opioid-mediated negative feedback mechanisms (in conjunction with similar ATP-mediated actions) tonically brake the secretory activity of the chromaffin cells. However, with strong stimulation, the voltage-dependent effects of the opioids are lost; thus, the secretion of catecholamines (and enkephalins) is facilitated. The

coproduction of enkephalins may thus ensure that there is minimal secretion of catecholamine from the chromaffin cells under basal conditions, but may permit a sharp increase when the animal responds to stress by increasing the frequency of impulses in the sympathetic nerves controlling the adrenal medulla.

In summary, enkephalins cosecreted into the circulation with epinephrine when the adrenal medulla is stimulated can have distant actions. Within the adrenal medulla, enkephalins automatically moderate or inhibit epinephrine release, except when the chromaffin cells are strongly stimulated.

Opioids and Stressor Processing

Pain

The origin of pain is normally at the site of intense stimulation or tissue damage, causing the discharge of impulses in a specialized set of nerve endings (nociceptors). The extent of excitation of these nerve endings is related primarily to the intensity of the painful stimulus, but this is regulated by local chemical signals, including opioid peptides, released when tissue is damaged. Information about painful stimulation is carried as impulses in afferent nerve fibers (especially the small diameter, unmyelinated, and slowly conducting C fibers and the myelinated A δ fibers, responsible for dull and sharp pain, respectively). These synapse in the dorsal horn, in the substantia gelatinosa (lamina II) and lamina I, respectively, of the spinal cord. Through their long axonal projections in the spinal cord, postsynaptic neurons convey the nociceptive information to the brain. Transmission at these synapses is subject to modulation by locally released neurotransmitters, including opioid peptides. Modulation in the dorsal horn alters the perception of the pain and its impact as a stressor, enhancing (hyperalgesia) or decreasing (analgesia) its effects. The application of morphine to the spinal cord (intrathecal injection or infusion) is highly effective in producing analgesia.

Endogenous opioid and opioid receptor expression in pain-mediating cells

There is a high density of all three types of opioid receptors on the nerve fibers in laminae I and II of the dorsal horn. The C (or A δ) fiber neurons have their cell bodies in the dorsal root ganglia and express μ -opioid receptors in particular, but also δ -receptors, transporting the receptors into both their peripheral and central processes (Figure 1, iii). Postsynaptic neurons also have opioid receptors, including κ -opioid receptors. Opioids (enkephalins) in the substantia gelatinosa are produced by the C fiber neurons themselves and by local neurons in the dorsal

horns. Opioids in the dorsal horns include enkephalins, dynorphins (especially in the substantia gelatinosa), and endomorphin 2 (in the nerve fibers of the afferent dorsal root ganglion neurons). Presynaptic opioid actions in the spinal cord involve hyperpolarizing the terminals by activating K^+ channels so that there is less transmitter released when the impulses triggered in the periphery arrive. The main excitatory transmitter released from the C (or A δ) fiber neurons is glutamate (acting through NMDA receptors), but its effects are enhanced by the coreleased peptide substance P. Substance P and δ -opioid receptors are found together in the secretory vesicles in the nerve terminals of dorsal root ganglion neurons in the dorsal horn. Thus, the opioid receptors are exposed for opioid binding as the nerve terminals release their excitatory neuropeptide. The inhibition by opioids of the release of these excitatory transmitters consequently brakes the activation of relay neurons in the spinal cord that would otherwise have been excited further. Opioids also inhibit the postsynaptic neurons directly, which are probably excitatory interneurons. These oppose the excitatory actions of glutamate through NMDA receptors and, for κ -agonists, also oppose glutamate actions via AMPA receptors.

Opioids in inputs to pain-processing systems The brain influences the processing of nociceptive input in the spinal cord, partly by activating the opioid interneurons in the dorsal horns. There are descending fibers, in the dorsolateral funiculus of the spinal cord, from neurons in the brain stem to the dorsal horns (Figure 1, i, iii). These neurons are in the raphe nuclei and locus coeruleus, and they receive input from the PAG and, in turn, from the reticular formation, limbic system, cerebral cortex, and thalamus. They produce monoamines as their transmitters (serotonin, 5-HT; or norepinephrine), and opioids are important in regulating their activity as well as their actions in the spinal cord. When these areas are stimulated, especially the PAG, opioids are released in the dorsal horns, which act via δ -, κ -, or especially μ -opioid receptors and inhibit nociceptive neurons; analgesia results, which is reversed by naloxone. Opioid application in these brain-stem regions has the same effect as stimulation. Hence, endogenous opioids acting on these groups of neurons in the brain, via δ -, κ -, or μ -opioid receptors, are important in controlling or filtering indirectly the flow of nerve impulses from the spinal cord that cause the sensation of pain. Opioids may act directly on these neurons or on the terminals of their afferent neurons; for example, met⁵-enkephalin acts like this after its release from presynaptic terminals on locus coeruleus neurons. Appropriately, the descending mechanism is activated

by stressors that are likely to lead to pain, giving rise to stress-induced analgesia. Pain pathways continue to ascend to the thalamus and onward to the limbic system and cerebral cortex, affecting mood and bringing the sensation of pain into consciousness. The analgesic actions of morphine include actions at the level of the limbic system and cerebral cortex, which modify further the impact of a painful stressor on the activity of the HPA axis and other stress response mechanisms.

Stress-Induced Analgesia

It has long been recognized that in the heat of battle the perception of pain from an injury can be suppressed. Experimental studies on rats, first reported in 1976, showed that inescapable foot shock increases the pain threshold and that this is partly reversed by naloxone, indicating the involvement of endogenous opioids. The increase in pain threshold is generally tested with a different stimulus from that inducing analgesia, such as, the measurement of tail-flick latency. The mechanism of this stress-induced analgesia involves the pathway previously described, from the brain to the spinal cord; thus, other neurotransmitters involved include monoamines (norepinephrine, 5-HT, and histamine). Microinjections of antagonists have shown that opioid mechanisms (δ - and κ -, as well as μ -, opioid receptors) are activated in the brain stem and spinal cord (Figure 1, i, iii). There are differences between individuals or strains of rats or mice in the analgesic response to a stressor, and these are related to genetic factors and the density of μ -opioid receptors in the brain. Also, transgenic mice that have a disruption of the prodynorphin gene, or that do not produce β -endorphin, do not show swim-stress-induced analgesia, which is also suppressed in normal mice by the administration of a κ -opioid receptor antagonist. Stress-induced analgesia can be conditioned, and the conditioned response (analgesia) is prevented by naloxone; thus, the expectation of a painful or stressful stimulus evidently activates brain opioid mechanisms to reduce the anticipated pain. In particular, δ - and μ -opioid receptors (rather than κ -opioid receptors) are involved. An analogous opioid-mediated analgesic effect of anticipated pain has been shown in humans. Such conditioning involves higher brain levels. In contrast, lesion studies show that the PAG and structures more rostral are not necessary for analgesia induced by physical pain (foot shock), which is mediated via the brain stem, particularly the nucleus raphe alatus, and by the spinal cord. Presumably, the ascending information about the foot shock pain stimulates the opioid mechanisms in the brain stem.

Because a stress response (adrenocortical activation) is not essential for stress-induced analgesia,

although basal corticosteroid secretion has a permissive role, it has also been termed adaptive pain suppression. The involvement of opioids in this analgesia varies according to the pattern of stressful stimulation (naloxone reverses analgesia following intermittent but not continuous foot shocks) and its nature (analgesia with tepid- but not cold-water swimming is naloxone reversible and shows morphine cross-tolerance). Clearly, endogenous opioids are important in the analgesia produced by some, generally less persistent and less intense, stressors but not others. In contrast, nociceptin can block supraspinal analgesia, and the potentiation of mild stress-induced analgesia by an ORL-1 receptor antagonist indicates that endogenous nociceptin limits this analgesia. Nonopioid analgesia is a consequence of activation by other transmitters of the descending pathway that opioids can also activate; evidently, endocannabinoids act in the PAG to mediate nonopioid stress-induced analgesia. Lesion of the arcuate nuclei (the location of β -endorphin neurons) reduces opioid-mediated stress-induced analgesia, and transgenic mice with an inactivation of the POMC (β -endorphin) gene do not show normal swim-stress analgesia. In contrast, mice with an inactivation of the preproenkephalin A gene still show opioid-mediated stress-induced analgesia. Thus, β -endorphin, rather than an enkephalin, is the important opioid peptide in the brain.

In mice, social defeat induces analgesia, which is due to endogenous opioid action because it is prevented by naloxone and shows cross-tolerance to morphine. Because adrenalectomy or hypophysectomy does not affect this stress induction of analgesia, it is caused by opioids within the brain rather than by circulating opioids. In contrast, the removal of the pituitary gland or adrenal medulla (sources of β -endorphin and enkephalins, respectively) reduces the analgesia induced by foot shock or immobilization. Evidently, circulating opioids as well as opioids released within the brain can be involved in this analgesia.

An inescapable stressor can evoke learned helplessness (effects caused by the uncontrollability of events that are beyond the organism's control rather than by the events *per se*) as well as analgesia, and this too is opioid-mediated. The inhibition of motor activity, together with a reduced sensitivity to pain, may help the individual to cope or survive. Posttraumatic stress disorder may be modeled by the consequences of exposing an animal to inescapable electric shocks, with opioid-mediated stress-induced analgesia as a common feature.

In summary, pain control by opioids acting within the brain and spinal cord involves automatic feedback control at synapses in pain pathways *pari*

passu with noxious stimulation and activation of opioid neurons according to previous experience. The consequence is that these opioid mechanisms contribute to reducing pain sensitivity temporarily, for instance, during acute stress. Morphine mimics these actions to suppress pain.

Opioids and Immune Mechanisms: Inflammatory Pain

The functions of immune cells are modified significantly by the actions of glucocorticoids, and these actions are a major feature of the body's response to stress. However, the chemical messengers, including opioids and CRH, involved in the hypothalamus in regulating ACTH secretion also have important actions directly on immune cells.

Endogenous opioid and opioid receptor expression in immune cells The immune cells themselves produce opioids. T and B lymphocytes, monocytes, and macrophages contain the mRNAs for β -endorphin and met-enkephalin, and produce the peptides; expression is increased at sites of inflammation, and, significantly, immune cells contain pro-protein convertases, which process the opioid precursors. Furthermore, immune cells express the CRH1 receptor and CRH that is released locally from nerve endings stimulates inflammatory responses. One effect of CRH is to stimulate the release, from immune cells, of opioid peptides (especially β -endorphin, a product of the POMC precursor), particularly from lymphocytes migrating to the site of injury; some cytokines act similarly, as does lipopolysaccharide (bacterial endotoxin). The released opioid can then act locally to regulate the inflammatory process (Figure 1, iv).

Opioid effects on immune responses Morphine affects both cell-mediated and humoral immune mechanisms. Opiate (heroin) addicts have impaired immune mechanisms. This has implications for the progression of human immunodeficiency virus (HIV) infection in such individuals. Similarly, morphine has immunosuppressive effects in mice. *In vitro* studies showed that opioids (e.g., met-enkephalin acting through μ - or δ -opioid receptors) have direct inhibitory effects on a range of functions of immune cells, including the inhibition of killer activity (NO production) in macrophages and leukocytes. Lymphocytes express δ -, κ -, and μ -opioid receptors, and responses are mediated by $G_{i/o}$ -proteins and effects on calcium mobilization. Cytokines are signaling peptides important in the local regulation of immune cell function, and opioids inhibit the cytokine-induced activation and chemotaxis of granulocytes, acting to

desensitize cytokine receptors. However, the rapid effects of opioids can promote immune cell activity, and morphine or opioid peptides (β -endorphin or met-enkephalin) act as chemoattractants to leukocytes. Also, enkephalins stimulate the proliferation of B and T lymphocytes.

In addition, opioids released by immune cells, especially by polymorphonuclear leukocytes, at the site of inflammation have local analgesic actions, hence modulating stressful stimulation. Opioids, including morphine and enkephalins, applied to sites of injury, act through μ -opioid receptors (δ -opioid receptors are also expressed) on the nerve terminals, responding to painful stimuli (nociceptors) and to the chemicals released by local inflammatory cells, and reduce pain (Figure 1, iv). These antinociceptive actions are more effective, especially via μ -opioid receptors, if there is also local inflammation. This increased effectiveness is a result of increased opioid receptor expression in the C and A δ nerve-fiber terminals. It is partly a result of the disruption of the nerve sheath so that opioids have easier access. Opioids act on the nerve terminals to reduce their excitability, probably by opening K^+ channels, hyperpolarizing the terminals. This reduces both the initiation of nerve impulses and the release from these nerve terminals of chemical messengers (e.g., substance P), which promote the inflammatory process. The inhibitory action of opioids on immune cells will reduce their release of chemical pain messengers. Stress, such as swimming in cold water, activates the opioid antinociceptive mechanism in inflamed tissue. This perhaps indicates that circulating opioids, released during stress, may act peripherally at such sites (Figure 1, iv). The duration of action of peripherally released opioid peptides is limited by their inactivation by extracellular metalloproteinases, produced by immune cells themselves. Thus, it seems that the stimulated local release of opioids in the initial stages of inflammation may first promote activity of the immune cells and then dampen the response. At the same time, these local opioids reduce inflammatory pain. The nervous and immune systems interact in these processes. The development of drugs to target the peripheral opioid-mediated analgesic mechanisms may afford a new approach to controlling inflammatory pain.

Chronic inflammation leads to changes in the opioid mechanisms that modulate the processing of nociceptive input in the spinal cord. The expression of opioid receptors and opioid peptides in the dorsal horn afferents and neurons shows plasticity. In experimental polyarthritis (a stressful, painful chronic inflammatory condition in which pain sensitivity is locally increased, hyperalgesia), preproenkephalin and prodynorphin mRNAs in the dorsal horn are

strongly upregulated and the release of dynorphin in the spinal cord is increased. However, preproenkephalin mRNA expression in dorsal root ganglion neurons is reduced, as is enkephalin release in the spinal cord. Hence, the modulation of pain input in chronic inflammation changes from enkephalin to dynorphin mediation at this level. Nociceptin expression in different dorsal root ganglion cells is increased, and the proposed pronociceptive actions of this peptide may contribute to the hyperalgesia. There is an increase in the number of μ -opioid receptors (and a decrease in δ - and κ -opioid receptors) in the dorsal root ganglion neurons, but this may not result from increased gene expression. Opioid receptor upregulation in the dorsal horn lamina II does involve increased μ - and δ -opioid receptor gene expression in neurons in laminae I and II. These changes may explain the rapid increase in the effectiveness of morphine in inhibiting nociceptive dorsal horn neurons after the induction of focal peripheral inflammation. Clearly, because the chronic inflammatory condition is painful, the changes described do not succeed in preventing such pain.

In summary, the peripheral and central actions of opioids in the brain and spinal cord are complementary in controlling the transmission of information through pain pathways from a site of injury or inflammation. Opioids released at the site of inflammation, or arriving from the anterior pituitary or adrenal medulla, reduce the activity of immune cells and have local analgesic actions. Endogenous opioids reduce the perceived strength of the damaging stressor and thus dampen the HPA axis response to stress; with chronic inflammation, this mechanism may not function.

Opioids and Hedonic Appetite in Stress

It has been known for a long time that opiates and endogenous opioids stimulate the desire for sweets and that this craving is also a feature of stress. Naloxone reduces this desire in humans and in objective tests in laboratory animals. Hence, it has been proposed that the activation of endogenous opioid mechanisms is involved, when an individual is under stress, in enhancing the incentive value of rewarding stimuli, including the pleasant sensations from eating sweet and fatty foods. Consequently, endogenous opioids and their receptors are implicated as a cause of obesity due to hedonically driven overeating in chronically stressed individuals. A consequence of such overeating in animal models is the reduction of the activation of the HPA axis, evidently by a signal from the enlarged abdominal fat store.

Evidence that endogenous opioids are released as a result of consuming sweet foods includes the finding

that this results in analgesia reversible by naltrexone, a long-acting version of naloxone. Studies on mice with transgenic manipulations of the POMC and proenkephalin-A genes so they do not produce β -endorphin or enkephalins showed a reduced incentive to obtain sweet nutrient over and above their need for calories; these findings implicate both of these endogenous opioids in the stimulation of hedonic appetite. In contrast, although nociceptin can also stimulate feeding, it does not stimulate hedonic appetite, so is unlikely to be involved in increasing the desire for sweets and fatty food in stress.

The causal relationship between the activation of brain endogenous opioid mechanisms and the palatability of food or drink extends to the desire to drink alcohol in susceptible individuals; accordingly, naltrexone can be prescribed for the treatment of alcoholism. Further evidence that some actions of nociceptin are functionally opposed to those of opioids is that nociceptin given in the brain in rats acts like naloxone to reduce the stress-induced reinstatement of alcohol-seeking behavior in rats with a previously established preference for alcohol. This has prompted research to develop a nonpeptide ORL-1 agonist to treat alcoholism.

The involvement of endogenous opioids in the normal regulation of appetite and food intake without stress, studied for over 40 years, is complex. Multiple opioid peptides and multiple receptors are involved at several sites in the brain. For instance, male mice genetically engineered so they do not produce β -endorphin eat more and become obese, indicating an anorexigenic role for this opioid in normal appetite regulation and contrasting with its orexigenic actions on hedonic appetite. Because naloxone still reduces food intake in these mice, it is clear that opioids other than β -endorphin usually mediate the orexigenic actions that have previously been suspected to be due to β -endorphin. Sites in the brain where opioids have been shown to stimulate eating have been identified by seeking evidence of opioid modulation of the activity of pools of neurons in discrete brain areas known to be involved in appetite regulation (Figure 1, v). These studies involved the microinjection of opioid receptor agonists and antagonists into these brain regions, sometimes into different sites in the same animal, to investigate opioid-mediated interconnections. The effects of such local opioid interventions on appetite, measured in a range of tests with food intake as an end point, and on the activities of neurons in the treated area have then been studied. Neuronal activity has been evaluated principally by the postmortem identification of stimulated immediate-early gene expression, using Fos immunocytochemistry. Of particular interest in the

context of stress-induced eating is that fat or sugar intake is stimulated by the microinjection of μ - or δ -, but not κ -, opioid agonists into the shell of the nucleus accumbens. This nucleus receives a dopaminergic input from the ventral tegmental area and is a key part of the mesocorticolimbic system, the reward circuitry that is implicated in drug dependence, including alcoholism. Opioids act in the shell of the nucleus accumbens, via μ - and δ -opioid receptors to increase the release of dopamine, which underlies hedonic sensation. Here the local injection of a μ -opioid receptor agonist stimulates the ingestion of a sweet or fatty meal, and especially a fatty one – increasing almost threefold the amount of fat ingested. The double-injection technique (opioid agonist microinjected into one site, and opioid antagonist microinjected into another) has shown there are opioid-mediated interactions between the nucleus accumbens and the central nucleus of the amygdala, with a μ -opioid agonist stimulating feeding and reciprocal opioid connections between the nucleus accumbens shell and the ventral tegmental area. This reciprocal opioid connection promotes feeding via μ - and δ -opioid receptors. Naltrexone, given systemically, activates neurons in the nucleus accumbens shell, as indicated by Fos expression, and prevents the activation of presumably different neurons in this structure that otherwise follows the ingestion of a palatable meal. Appropriately, the consumption of a sweet, fatty meal activates central β -endorphin neurons. These opioid-driven mechanisms for individuals preferring to ingest energy-rich sweet and fatty foods, notably when they are stressed, can be seen as having a survival advantage in that energy storage is favored. However, with the superabundance of such foodstuffs in advanced societies, these opioid-based reward mechanisms evidently contribute to obesity as a consequence of stress.

The involvement of multiple opioids and their multiple receptors in appetite control, and the multiple other roles of endogenous opioid mechanisms, means that opioid antagonists are insufficiently precise for use in obesity treatment. Instead, recent discoveries have revealed the roles of endocannabinoids and several nonopioid neuropeptides in the regulation of appetite, including α -melanocyte stimulating hormone (MSH), which, like β -endorphin, is a POMC derivative produced by arcuate nucleus neurons, and these have become the focus of attention as novel drug targets.

In summary, endogenous opioids regulate activity in the reward circuitry in the brain, increasing appetite for sweet and fatty foods and the desire for alcohol. The seeking of such hedonic rewards is increased by stress, and opioids drive this behavior.

Opioids, Stress, and Reproduction

Opioids and the Hypothalamic-Pituitary-Gonadal Axis

Reproductive capability depends primarily on the intermittent, approximately hourly, synchronized discharge of gonadotropin-releasing hormone (GnRH) neurons in the anterior hypothalamus/preoptic area. The GnRH so released into the hypothalamo-hypophysial portal system drives gonadotropin secretion from the anterior pituitary gland, which in turn stimulates the sex steroid- and gamete-producing activities of the ovaries or testes. The suppression of this GnRH pulse generator leads to failing gonadal function and to diminishing reproductive capacity or sexual desire. The striking consequence in females of many species is the failure of ovulation and in women the accompanying cessation of the menstrual cycle. Because these effects are a consequence of the suppression of the GnRH pulse generator, this is hypothalamic amenorrhea. Stress depresses reproductive activity in this way, although actions of stress hormones on the anterior pituitary gonadotrophs or gonads may also be involved. Stress inhibits the activity of GnRH neurons through the indirect actions of CRH within the brain via an opioid mechanism in both males and females.

Endogenous opioid effects on gonadotropin secretion during stress: males and females There are many β -endorphin terminals, along with CRH nerve terminals, in contact with, or in the vicinity of, the GnRH neurons (Figure 1, i). It is important to note that endogenous opioids also play an important role in the normal regulation of GnRH neurons in active reproductive life, being involved in the interplay between the sex steroid hormones and the neurons. Furthermore, it does not follow that because opioids have been involved in suppressing reproductive function that simply antagonizing opioid actions will reactivate GnRH neurons. Different processes are involved in reactivation. Hence, in women with amenorrhea associated with intensive physical training, naloxone may have no effect. The suppression by restraint stress of the luteinizing hormone (LH) surge in rats that occurs every 4–5 days and triggers ovulation is evidently not caused by endogenous opioids because naloxone does not prevent this.

An acute stressor in intact males can increase LH and testosterone secretion transiently, perhaps aiding aggressive responses. In castrated male rats, foot shock stress decreases LH secretion rapidly, which is reversed by the injection of antiserum to β -endorphin or dynorphin or an irreversible μ -opioid receptor

antagonist into the cerebral ventricles, with no effects of δ -opioid receptor ligands. β -Endorphin or CRH injected centrally inhibits LH secretion. Furthermore, CRH is not effective after β -endorphin antiserum, so the inhibition by CRH evidently requires β -endorphin neurons. However, ablation of the PVN, and hence of the parvocellular CRH neurons, does not prevent the foot-shock-induced inhibition of the GnRH pulse generator in male rats and CRH neurons in the PVN evidently do not project to the GnRH neurons, so CRH neurons elsewhere may exert the inhibitory effects of stress on reproductive function. Also, calcitonin gene-related peptide (CGRP), given centrally, suppresses LH pulses, and this action, which is partly via the CRH neurons, is prevented or reversed by naloxone, indicating the mediation of CGRP actions by opioids. In male rats, the inhibition of LH secretion by acute (but not chronic) restraint is reversible by naloxone and hence involves endogenous opioids. Similarly, in female marmosets, aggression by a conspecific causes the naloxone-reversible inhibition of the GnRH pulse generator.

Fasting and insulin-induced hypoglycemia, produced experimentally, are stressors, and they reduce the frequency of GnRH pulses. This reflects a generally inhibitory effect of reduced energy availability on the GnRH pulse generator, so that reproductive activity is suppressed when it would strain further the individual's ability to support its own needs. Leptin is an important signal from adipose tissue in this regard, and the suppression of central kisspeptin production is involved; kisspeptin is a hypothalamic peptide essential for the reactivation of GnRH neurons at puberty. The inhibition of the GnRH pulse generator by fasting or hypoglycemia, which is evident only in females or males with sufficient estrogen or testosterone, respectively, is mediated through μ -opioid receptors; a similar suppression in rhesus monkeys does not involve opioids. The requirement for sex steroids may relate to their stimulatory effects on POMC neurons in the arcuate nucleus. CRH can, with vasopressin, stimulate the release of β -endorphin from these POMC neurons, and this could be the link for the hypoglycemic inhibition of the GnRH pulse generator. Opioids from the adrenal medulla may be involved because the removal of the adrenal medullae abolishes this inhibition. Glucose deprivation stimulates PVN CRH neurons by increasing norepinephrine release, inhibiting GnRH neurons indirectly. The inhibitory actions of CRH on the cell bodies of the GnRH neurons are partly blocked by local μ -opioid receptor antagonists, and thus endogenous opioids released in the vicinity may mediate these CRH actions. However, GnRH neurons do not express

opioid receptor genes, so opioid actions are indirect. Specifically, opioid action in the medial preoptic area seems important, where β -endorphin-containing terminals are found, with noradrenergic and neuropeptide Y (NPY)-containing terminals, on neurons projecting to the PVN. Dynorphin and enkephalin-containing terminals are also found in the vicinity of GnRH neurons. In addition, CRH can act by stimulating endogenous opioid release (β -endorphin or met-enkephalin) in the median eminence, with consequent inhibition, via μ -opioid receptors, at the level of the GnRH nerve terminals. It is not known which endogenous opioid neurons are activated by stress to inhibit GnRH neurons.

Endogenous opioid effects on gonadotropin secretion during stress: males In males, stress decreases the circulating testosterone levels, as we expect from the inhibition of LH secretion. Leydig (interstitial) cells of the testis are the principal source of the male sex steroid hormone, testosterone, but also express the POMC gene, producing β -endorphin under stimulation by gonadotropin along with dynorphins. Sertoli cells (nurse cells for spermatogenesis in the seminiferous tubules) have opioid receptors and produce enkephalins. Opioids affect spermatogenesis through Sertoli cells and testosterone production via any Sertoli cell effects on the nearby Leydig cells. Locally administered naloxone can increase testosterone production. These mechanisms are evidently activated during stress so that immobilization for several hours decreases the circulating level of testosterone by approximately half, due to an action of opioids within the testes involving reduced sensitivity to gonadotropins. It is not clear how the stressor can activate intratesticular opioid mechanisms, but this seems to be a way in which the sex drive may be indirectly reduced during stress.

In summary, endogenous opioids, in particular β -endorphin, mediate the suppression of the pulsatile activity of GnRH neurons and hence mediate the inhibition of gonadotropin secretion and gonadal function that may occur with stress.

Conclusion

In sum, endogenous opioids act as censors, forbidding excessive stimulation by noxious inputs, opposing the actions of chemical messengers acting on neural circuits that favor greater responses to stressors. Endogenous opioids can make the outside world seem less hostile, albeit less sexually interesting, and increase the appetite for rich food.

Models of Motivation and Optimism

Goals, Stress, and Optimism

Effects of Optimism on Well-Being

Future Directions

Glossary

<i>Coping</i>	Attempts to deal with obstacles to goal attainment and with losses.
<i>Cross-sectional study</i>	A study in which the predictor and outcome variables are assessed at same point in time.
<i>Expectancy-value theories</i>	Models of motivation in which expectancies and values (goals) interact to determine behavior.

Explanatory style

A person's characteristic way of explaining prior negative (and positive) outcomes.

Optimists

People who generally expect to obtain favorable personal outcomes in the future.

Prospective study

A study in which the predictor and outcome variables are assessed at some appropriate baseline and then the outcome variables are reassessed at a later time.

Stress

Experience that arises when people have difficulty moving toward their goals.

Models of Motivation and Optimism

Optimists are people who hold generalized positive expectations for the future. They expect good things to happen to them, not bad things. Pessimists are just the reverse. They expect to miss out on the good things in life and to experience things that are bad. Research suggests that individual differences in optimism and pessimism may play an important role in the manner in which people react to stressful circumstances. To understand the nature of the effects, it is important to understand the broader theoretical context in which research on optimism and pessimism is

embedded. It is also important to understand how goals and the pursuit of goals are involved in creating stress.

Expectancies are pivotal in most contemporary theories of optimism. Defining optimism and pessimism in terms of expectancies creates a link to expectancy-value theories of motivation (some of which date back to the first few decades of the twentieth century). Expectancy-value models assume that behavior occurs in order to attain desired values or goals. If engagement of effort is to occur, there must be a goal that matters enough (has enough value) to try to reach it. The other element in the equation is expectancy: Confidence or doubt that the goal will be obtained. If the person lacks confidence, again there will be no action. If the person loses confidence along the way, action will stop. Only when confidence is sufficiently high will the person act and remain engaged in goal-directed efforts.

Expectancies exist at many levels of generality. A patient lying in a hospital bed recovering from an automobile accident can have a variety of different expectancies. She can have an expectancy about being able to move her index finger one more centimeter forward, an expectancy about being able to get out of bed unaided by next Saturday, and an expectancy about fully recovering from the trauma in the long run. Presumably, the principles embodied by expectancy-value theories pertain equally well to expectancies that are specific in nature and expectancies that are more general. They should even apply to the most general kinds of expectancies, those that characterize optimists and pessimists. The confidence that is at issue is simply broader in scope, relevant to a greater class of situations and behaviors.

Goals, Stress, and Optimism

Expectancies are important facets of expectancy-value theories, but so are goals and values. The emphasis on goals meshes well with aspects of contemporary theorizing in personality and social psychology. Recent years have seen a reemergence of interest in goal constructs. One prevailing view is that human behavior is organized around the pursuit of goals – trying to attain things that are desired and avoid things that are not. Because of differences in emphasis, theorists use different terms to refer to goals, including current concerns, personal strivings, personal projects, and life tasks. Goals that are even broader in nature carry labels such as possible selves and self-guides.

Although these various goal constructs certainly differ among themselves in ways that are far from

trivial, they also share an underlying commonality. All include the idea that goals energize and direct activities. All include the sense that goals give meaning to people's lives and that understanding the person means understanding the person's goals and the organization of those goals. As such, goals are seen as providing the structure that define people's lives, imbuing lives with meaning, both in the short run and the long run.

Goal constructs provide an interesting window on the experience of stress and coping. From this vantage point, stress occurs when people experience difficulty moving toward desired end states or difficulty keeping away from end states that are unwanted. Stated somewhat differently, stress occurs whenever impediments to goal attainment are encountered. From this perspective, coping involves efforts to create conditions that permit a person to continue to move in the right direction (toward the desired goals or away from the undesired goals) or to disengage from goals that are seen as no longer attainable. Thus, stress and coping are not seen as distinct classes of phenomena but, rather, are seen as arising within the dynamics of normal goal-related self-regulatory processes.

What determines how a person reacts to the blockage of goal-directed activities? Expectancy-value theories suggest that the key determinant is the person's confidence or doubt that goal attainment will eventually occur. Thus, when confronting minor challenges, optimists take a posture of confidence and continue to persist in their goal-directed efforts, even if progress is difficult or slow. Pessimists are more doubtful and reserved in their efforts. This divergence should also be displayed as the threat to goal attainment becomes more extreme. Optimists are likely to believe that the adversity can be handled successfully; pessimists are likely to anticipate disaster. To the extent that continued engagement in goal-directed efforts is adaptive, optimists should experience a coping advantage over pessimists.

Effects of Optimism on Well-Being

Measuring Optimism

Research on the beneficial effects of optimism has flourished over the past 20 years. This research has tended to take two different routes to assessing optimism, leading to two somewhat distinct literatures. One approach measures expectancies directly, asking people to respond to statements such as "I'm optimistic about my future." The second approach is more indirect. It assesses expectancies by examining attributional style, the characteristic manner in which a

person explains prior events. Bad outcomes that are explained in terms of causes that persist into the future, influence a broad range of events, and involve an aspect of the self are thought to be pessimistic in nature in that they carry the implication that negative outcomes will continue to occur. The opposite attributional style – explaining negative events in terms of causes that are more time limited, narrow in their effects, and external to the self – are thought to reflect a more optimistic orientation. Although in principle attributional style can be assessed with respect to both negative and positive prior events, in practice assessment is usually limited to negative outcomes only.

Psychological Well-Being

Dozens of studies have been conducted examining the relationships between optimism, pessimism, and distress among groups of people undergoing adversity of one type or another. The range of stressors embodied by this research has been extremely varied. Studies have examined the experiences of students entering college, employees of businesses, and survivors of missile attacks. Studies have measured the reactions of people caring for cancer patients and people caring for patients suffering from Alzheimer's disease. Research has examined the experiences of people dealing with medical procedures such as childbirth, abortion, coronary artery bypass surgery, and attempts at *in vitro* fertilization, as well as heart and bone marrow transplantation. Yet other studies have looked at how people deal with a diagnosis of cancer, the pain of arthritis, and the progression of AIDS.

The results of these various studies all point in the same direction: optimists experience less distress during times of adversity than do pessimists. This conclusion holds for studies that are cross-sectional in nature – that is, those that assessed optimism and distress at the same point in time. This conclusion also holds true for studies that are prospective in nature – that is, those that assessed optimism and distress at some appropriate baseline and then reassessed distress at a later time. The results of the prospective studies are particularly noteworthy in that they suggest that optimism is associated with beneficial changes in distress over time. Thus, these prospective studies also help to get around the potential problem of confounding optimism with subjective well-being, which is inherent in the cross-sectional research.

Physical Well-Being

Much more is known about the effects of optimism on psychological well-being than is known about the

effects of optimism on physical well-being. Still, a number of studies have explored the links between optimism and physical health and between optimism and parameters of physiological functioning. The findings from this body of research mirror those just presented with respect to psychological functioning: optimists typically show signs of better physical health or signs of more adaptive physiological responses when under adversity than do pessimists.

For example, compared to pessimists, optimists report fewer physiological symptoms during times of duress and maintain a higher health status across their lives. Other studies show that optimists are less likely to suffer negative side-effects from major surgery or to be rehospitalized within the first few months after major surgery. In a similar vein, less pessimistic people have been found to outlive people who are more pessimistic in outlook when diagnosed with a life-threatening illness such as recurrent cancer. They also exhibit less extreme cardiovascular reactivity during the course of their daily lives. On a somewhat different note, optimists tend to show signs of more adaptive immune functioning than do pessimists, but the evidence on this point is more mixed than on the other physical-health outcomes that have been examined.

Future Directions

At present, the evidence strongly indicates that optimism confers important benefits. Still, a number of questions remain for future research to resolve. First, there is a question concerning the structure of optimism and pessimism. Researchers tend to treat optimism and pessimism as though they were opposite poles of a single continuum. However, some evidence suggests that optimism and pessimism may represent related but independent dimensions. This is one question that researchers have been trying to sort out for a while and will continue to sort out into the future.

Second, little research has been directed toward understanding the developmental antecedents of optimism and pessimism. We do know from several studies that optimism and pessimism have a genetic basis. Less is known about the environmental influences on optimism and pessimism. What accounts for the nongenetic variation in optimism and pessimism? What kinds of life experiences cause a person to become more or less optimistic? These will also be important questions for future research to address.

Third, what can be done to turn pessimists into optimists? To date, relatively little research has concerned itself with generating and evaluating interventions designed to reduce pessimism. Given the toxic effects

of a pessimistic orientation, the future will no doubt see a significant increase in the number of studies that are designed to develop effective interventions to counteract the negative effects of pessimism.

Finally, it now seems well established that coping differences underlie the differences in psychological adjustment that emerge in the manner in which optimists and pessimists adjust to stress. Less clear are the biological and physiological mechanisms that underlie the differences in physical health outcomes that have been observed. The search for the biological pathways by which optimism gets translated into health outcomes will also occupy a substantial portion of the research landscape in the future.

Discovery of the Orexins

Orexins and the Stress Response

Orexin and Stress-Related Behaviors

Summary and Conclusion

Glossary

<i>Adrenocorticotrophic hormone (ACTH)</i>	A stress hormone that activates hormone secretion from the adrenal gland.
<i>Cerebro-ventricles</i>	Fluid-filled cavities in the brain where test compounds often are injected <i>in vivo</i> .
<i>Circumventricular organs</i>	Sites in the brain where there is no blood–brain barrier.
<i>Corticosterone</i>	A steroid hormone released from the adrenal gland during stress that facilitates energy delivery to the nervous system and stimulates the production of new glucose.

<i>Hypothalamus</i>	A brain region responsible for coordinating the appropriate endocrine, cardiovascular, and behavioral responses to stress.
<i>Prolactin (PRL)</i>	A hormone released from the anterior pituitary gland in stress that exerts multiple tissue-specific effects.
<i>Rostral ventrolateral medulla</i>	An important site in the hindbrain where neurons organize and control sympathetic efferent activity.
<i>Stress hormones</i>	Chemical messengers released from the anterior pituitary gland during physical or emotional stimuli.

Discovery of the Orexins

The lateral hypothalamic area (LHA) has long been considered to be an important site for the regulation of feeding behavior. In 1998, two groups independently identified the production of novel peptides in this region. deLecea and colleagues named these peptides hypocretins because of their apparent production in the hypothalamus and their structural homology to the members of the secretin family of peptides. Sakurai and collaborators named these peptides orexins on the basis of their ability when administered intracerebroventricularly (ICV) to stimulate food intake. It is now recognized that the peptides exert many physiologically relevant actions in brain, the majority of which are seemingly related to behavioral, endocrine, and cardiovascular responses to stress.

For convenience we use here the nomenclature advanced by Sakurai. Orexin A and orexin B are posttranslational products of the same prohormone (Figure 1). Two receptor proteins have been identified, the orexin type 1 receptor (OX₁R), which binds both peptides but prefers orexin A as a ligand, and the orexin type 2 receptor (OX₂R), which binds both peptides with approximately equal affinity. The two receptors are differentially distributed, as listed in Table 1.

The distribution of the orexin receptors predicted more biological actions than simply those related to food intake. Indeed, receptor localization in the dorsal raphe, tuberomammillary nuclei, and locus ceruleus (LC), areas known to be important in arousal state and sleep/wakefulness, predicted the eventual finding that the orexins are important determinants of sleep/wakefulness. The absence of the receptors in dogs and degeneration of orexin-expressing neurons in animal models and humans results in the syndrome narcolepsy/cataplexy. Thus, the major role recognized at this time for these peptides is one of arousal. Aspects of the narcolepsy/cataplexy syndrome highlight other reported biological actions of the orexins, particularly those related to stress.

Orexins and the Stress Response

Orexins and Cardiovascular Function

Soon after their discovery, the orexins were demonstrated by several groups to act in the brain to elevate

Figure 1 Structure of the orexins. From *Trends in Endocrinology and Metabolism* volume 11, 2000.

Table 1 Distribution of orexin receptor subtypes in brain regions important to the stress response^a

Brain site	OX ₁ R mRNA	OX ₂ R mRNA
Bed nucleus, stria terminalis	High	Moderate
Medial amygdala (nucleus)	Moderate	Low
Cortical amygdala (nucleus)	Low	Moderate
Periventricular thalamus (nucleus)	High	Moderate
Medial preoptic hypothalamus (area)	Absent	Moderate
Medial preoptic hypothalamus (nucleus)	Moderate	Moderate
Organum vasculosum lamina terminalis	Low	Moderate
Median preoptic area	Low	Moderate
Anterior hypothalamic nucleus	High	Low
Hypothalamic arcuate nucleus	Absent	High
Lateral hypothalamus (area)	Low	High
Medial paraventricular nucleus (parvocellular)	Absent	High
Lateral paraventricular nucleus (parvocellular)	Absent	Low
Posterior paraventricular nucleus (magnocellular)	Absent	Absent
Tuberomammillary nuclei	Absent	High
Ventromedial hypothalamus (nucleus)	High	Moderate
Dorsomedial hypothalamus (nucleus)	Absent/low	Moderate
Midbrain A4, A5, and A7 cell groups	High	Absent
Dorsal motor nucleus of vagus	Moderate	Moderate
Dorsal raphe nucleus	Moderate	Moderate
Locus coeruleus	High	Low
Nucleus of the solitary tract	Moderate	Low
Parabrachial nucleus	Absent	Low
Periaqueductal grey	Moderate	Moderate
Sensory and spinal trigeminal nuclei	Absent	Moderate
Substantia nigra (pars compacta)	Moderate	Moderate
Ventral tegmental area	Moderate	Moderate
Zona incerta	Moderate	Moderate

blood pressure and heart rate. The effects are mediated via the activation of the sympathetic nervous system, as demonstrated by the use of α -adrenergic antagonist blockade (phentolamine) and the demonstration of increased sympathetic nerve activity. Increased cardiovascular function was observed following the ICV or direct tissue-specific administration of the peptides into the area postrema, rostral ventrolateral medulla, and medial nucleus tractus solitarius; the direct effects on preganglionic sympathetic neurons in the intermediolateral cell column (IMDL); and the ability of intrathecal administration of orexin to activate these neurons. In addition, orexin has been shown to influence the excitability of paraventricular nucleus (PVN) parvocellular and nucleus tractus solitarius (NTS) neurons. This does not rule out the potential contribution of vagal withdrawal to the observed increased heart rate following central orexin administration. In fact, direct effects of orexin on neurons in the dorsal motor nucleus of the vagus also have been reported.

Cellular mechanisms of action In an attempt to determine the cellular mechanism of action of orexin

to raise blood pressure and heart rate by an action in the NTS, experiments were conducted in medullary slice preparations. Whole-cell recordings from NTS neurons in current clamp mode revealed that the depolarizing effect of orexin was maintained in the presence of tetrodotoxin, demonstrating direct postsynaptic actions of the peptide. In voltage clamp mode, orexin was observed to inhibit a specific potassium conductance (the sustained K⁺ current) and to activate a nonselective cation conductance, leading to depolarization. Later a G-protein signaling mechanism was demonstrated to activate phospholipase C and protein kinase C but not protein kinase A (PKA).

The cellular effects of orexin also have been characterized in the area postrema (AP), a circumventricular organ located adjacent to the NTS. In dissociated AP neurons, orexin similarly activated a nonselective cation conductance, leading to depolarization. In these cells, however, no effects on potassium currents were observed. The activation of a nonselective cation conductance also has been demonstrated in parvocellular PVN neurons, which may in fact have been preautonomic cells projecting

to sympathetic centers in the rostral ventrolateral medulla. As in the AP, there did not appear to be any action of orexin on potassium currents in neurons in parvocellular PVN.

In sympathetic preganglionic neurons in spinal cord, orexin's depolarizing effects are blocked by pertussis toxin, indicating a G-protein signaling mechanism. In these neurons, a PKA-mediated inhibition of potassium channels has been demonstrated. The direct effects of orexin to depolarize noradrenergic neurons in the LC occur due to decreased potassium conductance and the activation of an inward current. The exact receptor subtype responsible for these depolarizing actions of orexin in the NTS, AP, PVN, LC, or IMDL has not been identified; however, the similar (and in some cases diverse) signaling mechanisms described predict heterogeneity of receptor subtypes depending on tissue localization.

Physiological relevance of the pharmacological effects of orexin on cardiovascular function Mice in which the gene for orexin has been deleted (embryonic knockouts) and mice and rats engineered to suffer age-related loss of orexin neurons (orexin-ataxin 3 transgenes) display lower mean arterial blood pressures than their wild-type littermates under resting conditions and fail to mount a sympathetic response (increased heart rate or increased blood pressure) in the resident/intruder stress model. The reason for the lower resting blood pressures in these transgenic animals was established to be due to a loss of vasoconstrictor sympathetic tone because prazosin (α -adrenergic blockade) or hexamethonium (ganglionic blockade) failed to alter the already low pressures in these animals but brought pressures in wild-type littermates to levels similar to the transgenic animals. This was not accomplished by treatment with captopril (angiotensin-converting enzyme inhibitor) or a V_1 (vasopressin antagonist).

Does the syndrome narcolepsy/cataplexy in humans demonstrate compromised sympathetic function? Autonomic dysfunction has been reported in these patients, including the attenuation of cardiovascular reflexes to muscle contraction and the Valsalva maneuver. Frequent occurrences of orthostatic hypotension have been reported as well.

Neuroendocrine Actions of the Orexins

Orexin and the hypothalamic-pituitary-adrenal axis The presence of orexin receptors (Table 1) and broad distribution of orexin-positive nerve fibers in the hypothalamus suggested actions of the peptides on neuroendocrine centers in the diencephalon or the pituitary gland itself. Initial attention was drawn to potential actions in anterior pituitary gland because

orexin receptors are abundant in the gland and the peptide appears to be delivered to the median eminence, where it could gain access to the hypophyseal portal circulation. Although no significant effect of the orexins on prolactin (PRL) release were observed in dispersed anterior pituitary cell cultures, the release of the other major anterior lobe stress hormone, adrenocorticotrophic hormone (ACTH), was significantly affected by the concentrations of peptide in the nanomolar range. Basal ACTH release was not affected by orexin; however, corticotropin releasing hormone (CRH)-stimulated ACTH release was inhibited in a concentration-related fashion. The effect appeared to be mediated by the OX_1R because the median effective concentration (EC_{50}) for orexin A was at least 1 log lower than that for orexin B and because the inhibitory action of orexin was absent when the production of the OX_1R (but not the OX_2R) was compromised by antisense oligonucleotide treatment. Recently, the selective OX_1R antagonist has been demonstrated to also block the action of orexin A on CRH-induced ACTH release *in vitro*. Furthermore, the relatively selective OX_2R agonist (Ala¹¹, Leu¹⁴) orexin B did not exert actions similar to orexin A or orexin B. Orexin's action on the corticotroph appear to require the activation of a non-pertussis toxin-(non-PTX-) sensitive G-protein-coupled receptor to phospholipase C activation and the formation of inositol trisphosphate. In addition, the activation of PKC seems to be a necessary step in transduction of the inhibitory signal.

In the hypothalamus, orexin acts to stimulate the hypothalamic-pituitary-adrenal (HPA) axis by activating CRH-producing neurons. This was demonstrated by several groups using pretreatment with CRH antiserum or antagonists prior to the ICV administration of orexin. Whether this is a direct or indirect action of orexin on CRH-producing neurons in the parvocellular PVN is currently unknown, although single-cell the reverse transcription polymerase chain reaction (RT-PCR) approaches now employed in the authors' laboratories promise a future definitive answer to this question. Neurons in the PVN express both receptor subtypes, although the OX_2R appears more abundant. In addition, orexin-producing neurons that project to the PVN express glucocorticoid receptors, and thus the closed feedback loop of the HPA axis appears to include orexinergic neurons in the LHA (direct effects of orexin, of unknown origin, on adrenal steroid production and release have also been reported). As previously mentioned, direct postsynaptic effects of orexin on PVN neurons have been reported. The orexin effects on parvocellular PVN neurons, those projecting to median eminence or other brain sites (e.g., sympathetic

centers in the brain stem) are direct (i.e., postsynaptic) and are mediated by the activation of nonselective cation conductances. In magnocellular PVN, the depolarizing effects of orexin are indirect (i.e., tetrodotoxin blockable), involving a glutamatergic interneuron. Because high concentrations of arginine vasopressin (AVP) are capable of stimulating ACTH release from cultured pituitary cells *in vitro* and under at least some *in vivo* conditions the compromise of AVP action reduces stress-induced ACTH release, it is possible that the ACTH response to the ICV administration of orexin may be mediated by AVP release into the median eminence. The central administration of orexin has been reported to increase both CRH and AVP mRNA levels in the PVN; however, in hypothalamic explant cultures, orexin did not stimulate AVP release. Thus, it appears that the hypothalamic action of orexin to stimulate the HPA axis is mediated primarily by CRH release into the median eminence.

Orexin and prolactin secretion Controversy exists over the potential action of orexin on PRL secretion. Orexin, in log molar concentrations ranging from 1.0 pM to 100 nM, did not alter basal or thyrotropin-releasing hormone (TRH)-stimulated PRL release from dispersed anterior pituitary cells *in vitro*. However, when it was administered ICV some groups observed stimulatory and others inhibitory effects on PRL levels in plasma. The suppressive effects of orexin on *in vivo* PRL secretion were reported to be the result of increased dopamine turnover in male, but not female, rats. Evidence for a stimulatory role for orexin on PRL and luteinizing hormone (LH) releases come from fasting studies in which the pre-ovulatory PRL and LH surges, absent during fasting, were restored by central orexin administration. Even more support for the stimulatory actions of orexins comes from steroid-priming studies in ovariectomized rats, in which the PRL and LH surges were blocked by pretreatment with anti-orexin antibodies. Whether any of these pharmacological effects of orexin on PRL or LH secretion are physiologically relevant is unclear and may not be likely because orexin knockout mice are fertile and can nurse their pups. It is possible that physiologically relevant actions of the orexins on at least PRL secretion may not be related to reproductive function but instead to stress-induced hormone release. Thus, the actions of the peptide on tuberoinfundibular dopamine neurons of the arcuate nucleus, where the OX₂R is abundantly expressed, may be observed only in models of acute stress such as restraint (physical) or novel environment (anticipatory). The expression of early response genes in neurons of the LHA has been described in several experimental models of stress.

Orexin and Stress-Related Behaviors

The presence of orexin receptors and orexin-positive nerve fibers in central nervous system (CNS) sites known to be important in the arousal state, such as the LC and raphe nuclei, forms the anatomical basis for the effects of pharmacological doses of orexin on motivated and spontaneous behaviors. Several groups have described effects of orexin on locomotor behavior and general arousal state, and the obligatory role for endogenous orexin in sleep/wakefulness is well established. In our hands, the effects of orexin on general locomotor behavior and stereotypic behaviors parallel in dose relationship and time course the actions on sympathetic activity (i.e., blood pressure elevation). In addition, some of the feeding responses to orexin may be related to the peptide's ability to stimulate arousal, as well as exploratory and reward behaviors. These behaviors, observed following central orexin administration, mirror behaviors observed during stress; however, they differ from those observed following CRH administration, which are more anxiogenic in nature. There may be an important interplay between orexin neurons in the LHA and CRH neurons in the PVN. As already detailed, orexin appears to activate CRH neurons (resulting in ACTH release), and it has been reported that CRH receptors are present on orexin neurons in the LHA, where CRH itself exerts depolarizing effects. Thus, at least some of the behavioral arousal stimulated by CRH may be mediated by the effects of the peptide on endogenous orexin release.

The pharmacological actions of orexin on locomotor activity and arousal state are mirrored by determinations of orexin neuronal activity in these behaviors. Indeed, c-FOS expression correlates directly with wakefulness and locomotor activity, and the spontaneous activity of these neurons during such states has been characterized as well. One site of orexin action related to spontaneous locomotor activity is the PVN. In addition to stimulating feeding in the early light phase, orexin injection into the PVN increased spontaneous locomotor activity at all the times examined, and this was accompanied by increased oxygen consumption. The effect of orexin on spontaneous locomotor activity was antagonized by pretreatment with SB-334867 (an OX₁R antagonist). Those results suggest that physical activity independent of feeding is due to the actions of orexin in the hypothalamus. Indeed in recent studies, we observed that many, but not all, of the behavioral actions of exogenous orexin could be antagonized by pretreatment with the OX₁R antagonist, whereas some of the similar behavioral actions of the selective OX₂R agonist remain unaffected by OX₁R

antagonist pretreatment. Thus, both receptors may be responsible for differing behavioral modalities elicited by orexin administration. It will be important to determine the receptor subtype selectivity of the individual behaviors so that the roles played by each receptor in not only locomotor but also stress-related behaviors can be elucidated.

Non-Central Nervous System Sites of Orexin Action Related to Stress

Orexin receptors have been identified in non-CNS tissues, and significantly, the adrenal gland expresses both receptors but the OX₂R more abundantly. Orexin acts both *in vitro* and *in vivo* to stimulate corticosterone release, with orexin A being more potent than orexin B. This suggests a role for the OX₁R in the control of adrenal cortical function. The effect is selective (aldosterone secretion was unaffected) and is blocked by H-89 pretreatment *in vitro*, suggesting a signaling pathway involving adenylyl cyclase. Because the major site of orexin production was the LHA and plasma levels of the peptide are extremely low, it remained unclear that these pharmacological effects of orexin in the adrenal gland had any physiological correlate. However, it is now known that the orexins are also produced in the adrenal gland and thus may exert autocrine or paracrine actions in the gland. It should be remembered that the direction of blood flow in the adrenal gland is from the outer cortex to the inner medulla, and thus orexin produced in the adrenal cortex might bathe the medulla in relatively high concentrations, similar to the situation with corticosterone. At least in human pheochromocytomas, orexins act via the OX₂R to stimulate epinephrine and norepinephrine release, suggesting an action of orexin to regulate catecholamine release from the normal adrenal gland. Whether orexin production and/or release from cortex increases during stress is at this point unknown; however, it is tempting to speculate that the adrenal actions of orexin complement the peptide's actions in brain related to metabolism and stress.

Summary and Conclusion

Abundant evidence support a role for endogenous orexins in the regulation of sleep/wakefulness and metabolic state. Central to all the actions of the orexins is the consistent finding that multiple indicators of stress are revealed following orexin administration and some are absent when orexin production or action is compromised. Remarkable progress has been made in understanding the importance of the endogenous orexin system, largely due to the development of transgenic models of orexin peptide or receptor

compromise. In particular, the development of the orexin-ataxin-3 transgenic mice and rats has been a landmark in our ability to understand the broad impact of these peptides on multiple behavioral, endocrine, and cardiovascular systems. Now, with the availability of selective OX₁R antagonists and at least a relatively selective OX₂R agonist, additional elucidation of the sites and mechanisms of orexin actions in the brain can be accomplished. Because the replacement of the peptide restores normal sleep/wakefulness patterns in transgenic animals, the use of orexin or orexin analogs for the treatment of human narcolepsy/cataplexy holds much promise. Critical to the development of those potential therapeutic strategies is the recognition of the receptor subtypes responsible for the effects of orexin on cardiovascular and neuroendocrine function. Clearly, potential side effects related to cardiovascular control and hormone release are possible and should be monitored if orexin is to be tested for its therapeutic effect in humans.

Prevalence of Organ Transplantation

The Transplantation Process for the Individual Patient

Interventions to Minimize Stressor Effects during the Transplant Process

Glossary

<i>Graft rejection</i>	The process by which the body's immune response system attacks the foreign organ or tissue.
<i>Immuno-suppression</i>	The suppression of the immune response by an agent such as a chemical or drug in order to enhance the body's acceptance of foreign organs or tissue.
<i>Organ transplantation</i>	The process of removing an organ or tissue from one person's body and implanting it in another person's body.

Organ transplantation is increasingly often the procedure of choice for patients with end-stage diseases of the kidney, liver, heart, lung, pancreas, or intestines. Organ transplantation can significantly extend life, as well as dramatically improve the quality of

individuals' lives. Yet each step in the transplantation process – encompassing the initial evaluation and wait for an organ, the transplant surgery, postsurgical recovery, and living permanently with the transplant – is also associated with significant stressors. These stressors include both acute events and chronic, ongoing health and psychosocial strains. Across the entire process, transplant patients face and must adapt to changing health and functional capacity, altered social relationships, new perceptions of self, and revised life goals and plans. An understanding of both the nature of such stressors and individuals' reactions to them is critical for three reasons. First, as transplantation becomes more common, it is imperative that patients and their families know what to expect during the transplant process and thereafter. Education regarding likely stressors as well as potential benefits of transplantation will increase the likelihood that organ recipients will achieve the best possible quality of life (QOL) in the months and years after transplant. Second, it is only through knowledge about the nature of transplant-related stressors that we will be able to develop and test appropriate stress reduction interventions for transplant recipients and their families. Third, knowledge regarding transplant-related stressors, and reactions to them, also has value for understanding similar reactions to the experience of other life-threatening chronic physical illnesses, their treatment, and their long-term outcomes.

Prevalence of Organ Transplantation

Although the potential benefits of solid organ transplantation were first realized in the 1950s, it was not until the advent of modern immunosuppression in the 1970s and 1980s that organ transplantation fully evolved from an experimental procedure to the standard of care for many end-stage diseases. Today, the greatest obstacle to receiving a transplant is the shortage of donor organs. As illustrated in [Figure 1](#), the total number of individuals registered on the wait list for a transplant (including kidney, liver, heart, lung, heart-lung, pancreas, or intestines) far exceeds the number of transplants performed, and the gap continues to widen, despite the success of some social and governmental programs in increasing rates of donation. The lives of kidney transplant candidates can be maintained by dialysis during the wait for an organ. But for other solid organ candidates, for whom few or no such long-term alternative treatments exist, the consequence of the organ shortage is that a large proportion of them will die before a suitable organ becomes available.

In some areas of transplantation, living donor organs have helped to reduce waiting times and allow more candidates to receive transplants. For example, in the United States, living kidney donation – whether from a donor who is biologically or emotionally related to the recipient or from an anonymous,

unrelated donor – is almost as prevalent as deceased donor transplantation. Living liver donation is also becoming a viable option for some patients. [Figure 2](#) shows the total numbers of deceased donor transplants (and living donor transplants, where applicable) that were performed for each type of organ transplant in 2004 in the United States. Overall, kidney transplantation (whether from deceased or living donors) is the most common type of transplant performed, followed by liver, heart, pancreas, and lung transplantation. Intestine and heart-lung transplants are the most rare. Similar distributions are reported in other countries.

As shown in [Figure 3](#), survival rates following organ transplantation vary across organ type, but are good to excellent for many types of organs, especially in the early years after transplant. Kidney recipients, especially those with living donors, show the highest rates of survival. Even at 10 years posttransplant, 76% remain alive. Liver and heart recipients show slightly lower survival rates, but, even so, almost 75% survive at least 5 years posttransplant, and about 50% remain alive at 10 years posttransplant. Survival rates for intestine and lung recipients remain substantially poorer, especially in the long-term. But even these rates have shown marked improvements in recent years. Given that annual mortality rates range up to 30% or more among candidates awaiting transplant, it is clear that transplantation provides a significant extension of life for many patients.

The Transplantation Process for the Individual Patient

From the point of their initial contact and evaluation by the transplant team, patients and their families move through a relatively standard series of events

and time periods associated with the transplant process. The typical time line is shown in [Figure 4](#). The time line is punctuated by specific events that occur during the transplant process, and these events mark the onset and offset of important periods or stages, including the wait for a donor organ, the

Figure 4 Organ transplant timeline: critical events, time periods, and health and psychosocial issues. Abbreviations: tx, transplantation; QOL, quality of life. Adapted from Dew, M. A. et al. (2002). Psychosocial aspects of transplantation. Reprinted with permission from Medscape Transplantation. © 2002, WebMD, Inc.

perioperative recovery period, the early posttransplant months, and the longer-term posttransplant years. The duration of each of these periods can vary considerably, depending on such factors as the rapidity with which end-stage organ disease develops in a given patient, the availability of a living donor (when living donation is possible) or a suitable deceased donor organ, and the medical complications that may occur perioperatively or later posttransplant. However, the essential ordering of the events and time periods is similar for all patients.

Figure 4 also lists the typical health and psychosocial issues that are associated with each time period. Some of these issues are unique to specific time periods (e.g., continued deterioration of the native organ's function during the waiting period, or early posttransplant physical rehabilitation). Others are present across almost all of the periods (e.g., changes in QOL), although the central elements of concern to patients and their families in these areas vary across time. Each of the sections below considers the stressors and related health and psychosocial issues that are relevant to the major events and the time periods in Figure 4.

The Initial Evaluation for Transplant

The formal medical evaluation for transplant candidacy is often the first occasion during which patients and their families seriously consider transplantation as a therapeutic option. For both patients and their family members, the evaluation may evoke conflicting feelings, including relief and the hope of having a healthy future, fears about surgical risks and adapting to life with an organ from another person, worry about whether the patient will be judged to be a suitable transplant candidate, worry about the financial costs of transplantation, concerns that an organ will not become available soon enough to save the patient's life, and eagerness to try a new treatment option combined with reservations as to whether there might still exist other seemingly less drastic medical interventions. For all of these reasons, studies of psychological distress among patients and family members conducted at the time of the evaluation typically find that many respondents' distress levels are high. Symptoms of anxiety and depression have been noted most frequently, and distress in these areas may reach the level of diagnosable disorder in some individuals.

The evaluation for transplant is itself usually lengthy and complex because it is designed to assess all aspects of patients' medical and psychosocial status. Patients may be hospitalized during the several days of the evaluation in order to complete all required tests and procedures. An extensive array of medical and laboratory tests is required, and virtually all transplant programs consider patients' psychosocial and psychological histories. Although there is considerable variation across programs in the depth with which psychosocial history is probed, important elements that are usually evaluated to at least some degree include lifetime history and treatment of psychiatric disorder; lifetime history and current use of alcohol, nicotine, and other substances; current and past level of adherence to medical regimens; cognitive status and ability to understand what will be required for posttransplant care; social history including employment, financial circumstances, marital status, and availability of social supports from family and friends; personal views and expectations about the prospect of receiving a transplant; and personal strategies for coping with functional limitations due to health.

These psychosocial components are routinely assessed because patients' history and current status in these areas may influence their psychological adaptation to the wait for the transplant and to life after the transplant. However, these assessments often serve as important additional stressors to patients and families. They are stressful because of the personal nature of the questions as well as because the results may be used for decision making by the transplant team. Typically, these evaluations will contribute to judgments as to whether patients should be immediately listed as transplant candidates or whether they need to undergo additional interventions to improve their health status and adherence to the medical requirements set by the transplant team. For example, patients may be required to enroll in alcohol or smoking cessation programs before the transplant team will accept them onto the waiting list.

The Waiting Period

Many patients and their families perceive the waiting period to be the most psychologically stressful part of the transplant experience, due largely to patients' continued physical health deterioration and the inherent uncertainties about whether and when a suitable donor organ will become available. The duration of this period can vary from a few days (although brief waits are now rare) to several years, depending on the patient's medical status and other factors such as blood type and the patient's physical size. The geographical location of the transplant center can be a major

determinant of waiting time as well, since organs are allocated in many countries through a regional system that depends on the location from which the donor organ originated. Given the uncertainties of obtaining a donor organ, plus the risks of the transplant surgery itself (especially as the patient's medical condition deteriorates), patients and their families are faced with the mutually opposing prospects of preparing to live and preparing to die.

In the face of these stressors, the risk of significant psychological distress and cognitive impairment rises. Thus, as for many chronic disease populations, transplant candidates are much more likely to experience elevated distress and diagnosable depressive and anxiety-related disorders than nonpatient, community-based populations. Whether a particular transplant candidate is at greater risk for depression or anxiety appears to depend in part on their end-stage organ disease. For example, depression appears to be more common in kidney, liver, and heart candidates, while anxiety disorders – panic disorder in particular – are more often observed in patients with end-stage lung disease.

In general, the longer a patient waits for a transplant, the greater the psychological toll on the patient and family. However, it is noteworthy that an extremely brief wait (e.g., in the case of patients who have very rapidly declining organ function and are fortuitously able to undergo transplantation very quickly) may have negative psychological consequences as well. For example, it has been found that levels of anxiety and rates of anxiety disorders in the first year after transplantation are higher in patients who wait for very brief periods of a few months or less, compared to those who wait for longer periods. It is thus possible that the waiting period – despite its central elements of uncertainty and its associated risk for psychological distress when the wait is prolonged – can provide important time for patients to adapt to the idea that they need a transplant. If they do not have time before the surgery to adjust to the prospect of transplantation, the immediate consequence may be greatly heightened distress as they attempt to adapt to the transplant experience in the early postsurgical period.

Neurocognitive impairments are common in transplant candidates. For example, hepatic encephalopathy is prevalent in liver candidates and ranges from mild cognitive deficits to delirium and coma. Even patients with chronic liver disease who do not have hepatic encephalopathy may have cognitive and behavioral abnormalities as results of more subtle derangements of metabolic and detoxification functions. Cognitive deficits in heart candidates are extremely common once cardiac ejection fraction (a measure of the heart's ability to pump) drops below

30%; when brain perfusion is substantially inadequate, delirium results. Although kidney patients' conditions are generally more stable compared to candidates for other types of solid organs, subtle cognitive deficits often occur when patients are not well dialyzed.

Continued elevations in psychological distress and/or neurocognitive changes may have their own negative effects on other areas of patient well-being. For example, impaired patients may have more difficulty adhering to the medical regimen requirements set by the transplant team: they may have trouble following prescribed diets or abstaining from nicotine, alcohol, or other substances. These difficulties may arise not only due to impaired motivation (e.g., as a result of depression) but as a result of confusion and memory loss.

Finally, as patients' organ function declines, they may require increasingly complicated medical technologies and treatment regimens in order to maintain their lives. These treatments also serve as stressors that further tax patients' strained emotional and cognitive resources. The strain may extend to the family as well. The patient's marriage and relationships with primary family caregivers (who are most often spouses of adult patients and parents of pediatric patients) are particularly vulnerable due to role changes within the family and changes in daily living activities and schedules. The financial ramifications of these changes – arising from medical expenses, the inability of the patient to work, and/or the need for key family members to take substantial time off from work – can further add to strain within the family.

The Surgery and the Perioperative Recovery Period

This phase of the transplant process is characterized by major, but often positive, physical and emotional transitions. With improvements in procedures and medical care in the immediate days posttransplant, hospital stays have been dramatically reduced. For example, patients who receive the most common types of transplant (kidney, liver, or heart) are frequently able to be discharged in 7 to 10 days. However, as with all major surgery, the possibility for medical complications exists, and this, plus the patient's physical status immediately prior to surgery, will affect the speed of perioperative recovery.

During the first few weeks after surgery, most patients and their families voice high levels of optimism about the patient's prospects for recovery. Their central concerns usually involve how well the new organ is functioning and the probable speed of the patient's physical rehabilitation. These concerns are sometimes heightened by the brief postsurgical hospital stays. Moreover, the short duration of the

hospitalization is often perceived as stressful because patients and families typically receive many educational materials about life posttransplant during this time. (This information may have been provided before the transplant as well, but patients may have had difficulty absorbing it due to other stressors and/or cognitive impairment.) The positive feelings and optimism that often dominate after the surgery can interfere with educational efforts during the perioperative period because these feelings may lead patients and their families to be less able to accept and focus on information concerning potential complications, financial issues, and family difficulties that can arise posttransplant.

An additional source of stress arises from medication changes made in conjunction with the transplant. The immunosuppressants that transplant recipients will take for the remainder of their lives are introduced with the transplant, and they bring an extensive range of side effects. While some side effects abate with time, transplant patients – just like any other chronic disease population – will find that others appear to be permanent and unpleasant (e.g., tremor, altered body appearance, changes in sexual functioning, appetite changes). The new medications can also precipitate mood changes. For example, the introduction of corticosteroids can precipitate the onset or recurrences of mood or anxiety disorders. In addition, it is not uncommon for patients who were stabilized on psychotropic medications before transplant to have those medications abruptly discontinued after surgery. This can lead to rapid destabilization for patients, whose mood and/or anxiety disorders may quickly recur.

The First Year after the Transplant

For most patients, the first year posttransplant is a period of readjustment and rehabilitation, with gradual improvement in all domains of QOL, including physical, emotional, and social well-being. A frequent source of frustration for both patients and their families is the fact that the recovery process is generally considerably slower than they had expected. Moreover, important psychosocial elements of the transplant process may further prolong recovery and may also affect family members' well-being. These elements pertain to patients' need to (1) cope with common complications such as acute graft rejection episodes and infections, (2) alter their self-image from that of a critically ill or dying patient and resume a less illness-focused lifestyle, and (3) psychologically accept the fact that they have an organ from another person. Aside from these personal issues, patients may feel daunted by continuing financial issues related to the costs of the transplant, follow-up care,

and medications. In addition, in terms of interpersonal relationships, both patients and family members can be dismayed that the same marital, parent-child, or other family-related difficulties that existed before (and/or during) the period of critical illness and transplant surgery continue after the patient returns home. In fact, the stress of the waiting period may have held some relationships together temporarily, and these may then dramatically decline after the transplant.

An additional area of difficulty for many patients is adherence to the complex posttransplant treatment regimen. Not only must patients take multiple medications, but they also must complete routine medical follow-up evaluations and laboratory tests, monitor vital signs at home (e.g., blood pressure, temperature), follow exercise and dietary requirements, and adhere to restrictions on smoking, alcohol, and other substance use. Just as for most chronic disease patients who must adhere to a complex regimen, transplant recipients' adherence tends to worsen with time. This worsening itself can be a source of frustration (as well as a health risk) for patients, who may become quite discouraged at their inability to refrain from long-standing habits (e.g., smoking) or maintain new ones (e.g., exercise).

A likely result of these many concerns is that the likelihood of experiencing high levels of emotional distress, as well as clinically significant episodes of depressive and anxiety-related disorders, is higher during the first year posttransplant than during subsequent years. For most patients, distress levels gradually abate over the course of the year, and some psychiatric disorders – for example, posttraumatic stress disorder (PTSD) related to the transplant – appear to rarely if ever recur in later years. Individuals with PTSD related to the transplant appear to be unable to come to terms with the transplant experience and may experience flashbacks, nightmares, and extreme distress when thinking about one or more of the stressors that occurred during the waiting period, the surgery, and/or the perioperative recovery period.

Not only can the elements that serve as posttransplant stressors exacerbate psychological distress, but also such distress can itself serve as a major source of strain that, in turn, contributes to the worsening of these other stressors. Thus, for example, episodes of depression and anxiety can lead to increased difficulties in adhering to the medical regimen, as well as affect the patient's ability to cope with new medical complications or the need for rehospitalizations. There is evidence that, perhaps via these behavioral mechanisms, psychological distress can lead to poorer

clinical outcomes and reduced survival rates after transplant.

The Longer-Term Years after the Transplant

By the end of the first year after transplant, most patients have achieved their maximal level of physical rehabilitation and have psychologically adjusted to the transplant experience. Most then embark on a multiyear period in which graft functioning remains high and the rate of serious or life-threatening medical complications is low. Acute graft rejection episodes may be rare or relatively infrequent, compared to the first year after transplant. Patients' QOL in the areas of physical, emotional, and social well-being is often high, and rates of rehospitalization for rejection, infections, etc., are low. Some patients will develop new health problems, including diabetes, hypertension, and kidney disease, often as a result of long-term immunosuppression use. Patients are also at greater risk for cancers due to these drugs. Generally, however, patients' level of functioning remains quite high during these years.

Focal issues for patients and their families during these years pertain to maintaining as high a level of QOL as possible and postponing the effects of any decline in graft function or other complications for as long as possible. Economic and financial concerns related to costs of medications and continuing health care can become more important as the years go by. Nevertheless, psychological distress related to the transplant experience and its medical or psychosocial sequelae is uncommon during these years. Instead, patients' mental health is much more likely to be influenced by the same sorts of acute life events and chronic life strains experienced by other community populations. Indeed, the fact that nontransplant life stressors assume increasing prominence as predictors of emotional difficulties during these years attests to the fact that the vast majority of patients – even those who had great psychological difficulty immediately posttransplant – eventually are able to incorporate the experience into their lives and go on to focus on other things.

The Very Extended Years after the Transplant

We know the least about the stressors and psychosocial outcomes experienced by transplant recipients and their families beyond the 5-year anniversary of the transplant. Even in the 1980s and early 1990s, survival rates were sufficiently poor beyond this point that most clinical and psychosocial research did not consider these later-term years. Currently, however, with large proportions of patients surviving even well

Table 1 Examples of interventions that have been evaluated for their ability to improve patient and family psychosocial outcomes during the organ transplantation process

<i>Intervention</i>	<i>Sample and study groups</i>	<i>Design</i>	<i>Key results</i>	<i>Reference</i>
Education classes (3x/week for 6 weeks) plus exercise and weight training sessions (2x/week for 6 weeks), compared to education alone. Education focused on lung disease, home health care, stress reduction techniques	Nine lung transplant candidates randomized to education plus exercise (n = 5) or education alone (n = 4)	Randomized controlled trial; assessments pre- and postintervention, no blinding	No significant between-group changes, but global QOL and physical functional status significantly improved in both groups. No other improvements in physical, emotional, or social well-being	Manzetti, J. D., Hoffman, L. A., Sereika, S. M., et al. (1994). Exercise, education, and quality of life in lung transplant candidates. <i>Journal of Heart and Lung Transplantation</i> 13 , 297–305
Telephone-based sessions (1x/week for 8 weeks) compared to usual care (medical management by transplant team). Telephone sessions were supportive counseling with cognitive-behavioral techniques to address stress, health, and coping	71 lung transplant candidates randomized to telephone (n = 36) or usual care (n = 35)	Randomized controlled trial; assessments pre- and postintervention; transplant team blinded to treatment assignment; assessors not blinded	Telephone group had lower somatic, anxiety, and depression symptoms and better global QOL, global mental health, and perceived social support postintervention, controlling for baseline levels. No group differences in physical functional QOL or perceived stress	Napolitano, M. A., Babyak, M. A., Palmer, S., et al. (2002). Effects of a telephone-based psychosocial intervention for patients awaiting lung transplantation. <i>Chest</i> 122 , 1176–1184
Individual compared to group psychotherapy (1x/week for 12 weeks). Each condition used systemic integrative psychotherapy, which focuses on patient understanding of problems and means to address them	89 kidney recipients randomized to individual (n = 49) or group therapy (n = 40). A control group receiving no treatment (n = 37) was also enrolled	Partially randomized trial, with the control group enrolled after all other subjects; assessment pre- and postintervention (or at similar intervals in controls), with 3-, 6-, 9-, and 12-month follow-up. No blinding	Both intervention groups showed significant reductions in depressive symptoms that were maintained through 1 year postintervention. Control group showed considerably lower depressive symptoms than intervention groups at baseline, and symptom levels rose over time. By the final assessment, symptom levels in the three groups were similar	Baines, L. S., Joseph, J. T. and Jindal, R. M. (2004). Prospective randomized study of individual and group psychotherapy versus controls in recipients of renal transplants. <i>Kidney International</i> 65 , 1937–1942
Psychosocial intervention (4 months exposure to Internet-based program) compared to usual care (medical management by transplant team). Internet intervention included components to address health education, stress management, psychological well-being, and medical compliance	60 heart recipients receiving either the intervention (n = 20) or usual care (n = 40). Each recipient's primary family caregiver was also enrolled	Controlled trial with historical comparison group (usual care); assessments pre- and postintervention (or at similar intervals in controls); transplant team blinded to intervention participation; assessors not blinded to intervention participation but blinded to study hypotheses	Intervention group patients had significantly improved depression and anxiety symptoms, and caregivers had significantly improved anxiety and anger symptoms, relative to the comparison group. Social functioning QOL significantly improved in intervention patients and caregivers (not assessed in comparison group). Patient medical compliance did not change, but the subgroup who used the component of the intervention focused on the medical regimen showed significant improvement in keeping clinic appointments, completing blood work, and following diet	Dew, M. A., Goycoolea, J. M., Harris, R. C., et al. (2004). An internet-based intervention to improve psychosocial outcomes in heart transplant recipients and family caregivers: development and evaluation. <i>Journal of Heart and Lung Transplantation</i> , 23 , 745–758

Mindfulness-based stress reduction program (1x/week for 8 weeks). Program consisted of training sessions and daily practice of meditation and gentle yoga techniques	20 transplant recipients (2 lung, 12 kidney, 5 kidney-pancreas, 1 pancreas)	Single-group trial; assessments pre- and postintervention and at 3 months follow-up; no blinding	Sleep, depressive symptoms, and overall mental health significantly improved pre- to postintervention. At 3-month follow-up, sleep improvement was maintained, but depressive symptoms had worsened. At 3-month follow-up, anxiety symptoms were improved from baseline. No changes in global QOL, physical functional QOL, or medical adherence	Gross, C. R., Kreitzer, M. J., Russas, V. et al. (2004). Mindfulness meditation to reduce symptoms after organ transplant: a pilot study. <i>Advances in Mind-body Medicine</i> 20 , 29–29
Telephone-based QOL therapy compared to telephone-based support therapy (1x/week for 8 to 12 weeks). QOL therapy used cognitive-behavioral strategies to address patient-identified problems in various QOL domains. Supportive therapy involved listening and providing information about the transplant experience	35 lung transplant candidates randomized to QOL therapy (n = 17) or supportive therapy (n = 18)	Randomized controlled trial; assessments pre- and 1-month, 3-month postintervention; transplant team blinded to treatment assignment	While the groups were equivalent at baseline, the QOL therapy group showed significantly better global QOL, lower mood disturbance, and a better relationship with spouse/partner at 1 month postintervention. QOL and mood improvements were maintained at 3-month postintervention	Rodrigue, J. R., Baz, M. A., Widows, M. R, et al. (2005). A randomized evaluation of quality-of-life therapy with patients awaiting lung transplantation. <i>American Journal of Transplantation</i> 5 , 2425–2432

beyond 10 years posttransplant, it is critical that the stressors, as well as the continued benefits, of transplantation be more carefully delineated.

Many of the complications that began but remained at low levels of severity in earlier years become symptomatic and can lead to major functional limitations beyond 5 years posttransplant. For example, chronic graft rejection, kidney disease that progresses to kidney failure, complications of diabetes, and cancers all increase in prevalence. In all types of organ transplant recipients, kidney failure, due to long-term immunosuppressant use, can precipitate the need for a kidney transplant. Many individuals who had originally received nonrenal transplants (i.e., liver, heart, lung) do not expect to eventually need another type of transplant, and learning that they now need a kidney transplant can reawaken the depression and anxiety that they experienced while awaiting their earlier transplants. Individuals who originally received kidney transplants can experience a profound sense of bereavement as their renal graft fails and they return to dialysis.

Recipients of nonrenal transplants may develop chronic rejection that is sufficiently severe that they require a retransplant with a new heart, liver, or pancreas. Retransplantation of nonrenal organs remains considerably less successful than first-time transplantation. Therefore, progressive graft failure for these individuals is likely to be associated with increasing psychological distress because treatment alternatives and the potential for good outcomes are poor.

In short, the accumulating medical burden experienced by all types of transplant recipients in the extended years posttransplant is likely to lead to decrements in all areas of well-being and QOL. Some of the health-related stressors and their likely sequelae will be similar to those experienced during the end-stage organ disease that necessitated the original transplant. Other stressors may be more similar to those experienced by other chronic disease and late-life populations as they approach the upper end of their life expectancies.

Interventions to Minimize Stressor Effects during the Transplant Process

Transplant programs have attempted a variety of strategies to help patients and their families cope with transplant-related stressors and/or to minimize the stressors' impact on patients' emotional well-being and QOL. These interventions have included educational, psychotherapeutic, and self-help support

groups, patient-to-patient mentoring programs, and the provision of educational and referral materials using a variety of audiovisual formats. The effectiveness of the majority of these programs has not been empirically evaluated. A very small literature to date has tested psychosocial interventions that could be employed either face to face when organ candidates and recipients return to the medical center for care or by telephone or via the Internet. Examples of these interventions and study findings regarding improved patient and family psychosocial outcomes are listed in [Table 1](#). More extensive intervention development and testing for effectiveness are critical needs in this field.

Concluding Remarks

Glossary

Oxidative stress An imbalance between oxidants and antioxidants in favor of the oxidants, leading to a disruption of redox signaling and control and/or molecular damage.

Oxidative Stress Definitions

The imbalance between oxidants and antioxidants in favor of the oxidants, potentially leading to damage, forms the core of the definition of oxidative stress. In the biological-biomedical field oxidative stress denotes a disturbance in the pro-oxidant–antioxidant balance in favor of the former. Much experimental evidence now supports the thesis that the favorable aspects of aerobic life are also linked to potentially dangerous oxygen-linked oxidation processes. These are thought to form the basis of a number of physiological and pathophysiological phenomena and to participate in processes as diverse as inflammation, atherosclerosis, aging, carcinogenesis, drug action and drug toxicity, and defense against protozoa. Research on oxidative stress has intensified in recent years, as documented by the close to 42,000 entries at the ISI Web of Knowledge at the beginning of 2005, mainly about the role of oxidants in cellular redox signaling.

In view of the proliferation of publications using the term, a few cautionary words might be appropriate. How can oxidative stress be defined operationally? In the normal healthy state, oxidative challenge occurs in many cell types, but this alone does not constitute an oxidative stress. Likewise, a simple loss of antioxidants resulting from a limited nutritional

supply is not sufficient. However, when there is an increased formation of pro-oxidants such as hydrogen peroxide, which is accompanied by a loss of glutathione caused by the formation of glutathione disulfide (GSSG), we approach a definition. Even a severe loss of antioxidants, however, may still mean that there is no resulting damage. Novel roles of oxidants and antioxidants as part of signaling cascades and as mediators of adaptive responses have been unraveled, so it is possible that the time course and even the final outcome of a variety of diseases can be critically modulated by strengthening the antioxidant side of the balance.

This concept can be further refined by a better understanding of the normal biological uses of the reactive species that cause oxidative stress. The biological functions of reactive species that cause oxidative stress include fundamental processes such as the signaling of cell division and controlled cell elimination in the renewal of tissues. Furthermore, the balance of oxidants and antioxidants cannot be defined by a single entity. This has led to the view that multiple antioxidants are needed to protect cells and organs (the antioxidant network) and that different antioxidants are part of a protection system in specific disease processes. Following this line of reasoning, a refinement in the definition of oxidative stress has been suggested: “a disruption of redox signaling and control”. Such a definition focuses attention on abnormal routes of electron flow, which both alter normal physiological signaling and damage the macromolecular machinery.

As these definitions indicate, oxidative stress is a concept that is becoming clearer with further scientific development, each ramification and extension providing valuable further input. Redox chemistry involves reduction–oxidation reactions, so obviously tipping the balance in favor of the reductants may also cause an imbalance (reductive stress). A landmark in the development of oxidative stress is the 1954 work of Gerschman, who viewed oxygen toxicity along with x-ray irradiation. A summary of the accumulated knowledge of the field appears in a 1979 review of hydroperoxide metabolism in mammalian organs by Chance et al. In a 1970 study of glutathione in red blood cells, the effect of glutathione reductase deficiency on the stimulation of a hexose monophosphate shunt under oxidative stress was examined by Beutler and colleagues; this may have been the first mention of the term, at least in the title of a publication that is readily retrievable.

Related Terms

Dietary Oxidative Stress

The term dietary oxidative stress was coined by Levander in 1995. The relationship between oxidative stress and viral infections has been scrutinized in regard to this concept. This area has received much attention from food science and in functional food considerations. In a definition of dietary antioxidants published by the Food and Nutrition Board of the Institute of Medicine, National Academy of Sciences, in 2000, the term was defined as “as a substance in foods that significantly decreases the adverse effects of reactive species, such as reactive oxygen species, reactive nitrogen species, on normal physiological function in humans.” The ability of dietary anti- and pro-oxidants to affect oxidative stress has been widely discussed; Ames et al. have emphasized the presence of carcinogens and anticarcinogens in food.

Nutritional, or dietary, oxidative stress denotes a disturbance of the redox state resulting from excess oxidative load or from an inadequate nutrient supply that favors pro-oxidant reactions. The low intake of dietary antioxidants, including vitamins E and C, carotenoids, polyphenols, and other micronutrients (e.g., selenium), or the impaired availability of these antioxidants weakens the antioxidant network.

Postprandial oxidative stress, subform of nutritional oxidative stress, ensues from sustained postprandial hyperlipidemia and/or hyperglycemia and is associated with a higher risk for atherosclerosis, diabetes, and obesity. In Western societies, a significant part of the day is spent in the postprandial state. Unsaturated fatty acids incorporated into low-density lipoproteins (LDLs) and oxidized LDLs are an atherogenic factor. Lipid hydroperoxides present in the diet are absorbed and contribute to the pro-oxidant load. In hyperlipidemic and hyperglycemic subjects, endothelium-dependent vasodilation is impaired in the postprandial state, making postprandial oxidative stress an important factor modulating cardiovascular risk. Postprandial oxidative stress is attenuated when dietary antioxidants are supplied together with a meal rich in oxidized or oxidizable lipids. The ingestion of dietary polyphenols (e.g., from wine, cocoa, or tea) improves endothelial dysfunction and lowers the susceptibility of LDL lipids to oxidation. Polyphenols affect endothelial function not solely as antioxidants but also as modulatory signaling molecules.

Physiological Oxidative Stress

The fact that oxygen and its metabolites are not evenly distributed in organs and in subcellular organelles has led to the consideration that some sites are

under physiological oxidative stress. The mitochondria are considered to be a site of physiological oxidative stress; in fact, it is possible that basically all cells, in the quasi-normal situation, experience this form of normal challenge. In view of the growing interest in adaptive responses, it is of interest to identify the need for and the extent of the physiological exposure to oxidative stress. The basal level of macrophage and neutrophil activation, for example, may fall into this category. Likewise, the physiological activity of glutamate (NMDA) receptors could be included here. Thus, in specific locations in the physiological system there is a routine deployment of oxidants for normal functioning. A difficulty arises, of course, in defining the level at which the threshold for the pathological oxidative stress is transcended. It may be that the accumulation of damage products, as part of the general definition of oxidative stress, could be a useful parameter in this regard. The adaptation to oxidative stress, initially studied predominantly with bacteria (e.g., in the *oxyR*-response) has also been demonstrated in eukaryotes and may have interesting further functions in the mammalian organism. The field of cell and tissues responses in terms of gene expression in mammalian systems is developing rapidly. The term exercise-induced oxidative stress may also fall under the present heading.

Spontaneous mutations and aging can be considered to be the result of the exposure of the organism to oxidative stress, be it physiological or pathophysiological. The loss of the *oxyR* regulon, which controls the expression of a battery of oxidant-defense genes, leads to an enormous increase in the number of spontaneous mutations. The relationship of oxidative stress to the aging process has been studied in many ways.

Photooxidative Stress

The generation of oxidants by electronic excitation through impinging light represents a major part of photobiology. The photoexcitation of endogenous or exogenous sensitizer molecules, leading to the formation of reactive oxygen species, notably singlet molecular oxygen, can be the cause of molecular and structural damage. The wavelength ranges of biological importance are ultraviolet B (UVB) and ultraviolet A (UVA), but visible light and even infrared (IR) are known to generate photobiological responses. In human health, exposed tissues such as skin and the eye are the most studied. There is nutritional protection against this damage from sunlight in dietary micronutrients such as carotenoids and polyphenols (flavonoids). Photodynamic therapy (PDT) uses the biological effects of photooxidative stress.

Radiation-Induced Oxidative Stress

The chemical basis of radiation biology involves the generation of free radicals. This is a large research field, ranging from chemistry to the treatment of cancer.

Oxidant Stress

Oxidant stress has been used much less frequently. This term (although it sounds slightly ambiguous) may be considered to be more or less synonymous with oxidative stress.

Pro-oxidant Stress

Pro-oxidant stress was used by Levander in his 1979 work on metal toxicity, again using red blood cells as a model, in describing the effects of lead. Cerutti used the term pro-oxidant states in his analysis of the role of oxidants in tumor promotion.

Oxidative Stress Status

The problem of assessing the biological status of intact systems has been tantalizing. Noninvasive methods are preferable, and stable end points are good candidates for useful applications. Our early work was on using GSSG efflux as an indicator. Many efforts were directed toward this (e.g., the use of 8-oxodG or certain isoprostanes in urinary samples). The study of biomarkers of oxidative stress is being actively pursued.

Approaches are evolving to evaluate oxidative stress and its association with the risk of disease in humans. Most methods are currently available only on an experimental basis. A key approach involves genetic analyses of variations in key antioxidant systems that have been associated with disease risk. Clinical measures of the status of the nutritionally required antioxidants vitamins C and E are available, but there is no consensus on the spectrum of additional antioxidants that should be measured for an effective evaluation of oxidative stress-related risk. The glutathione redox state and the determination of reactive oxygen metabolites provide more dynamic measures of the ongoing balance of pro-oxidant and antioxidant processes. In the blood plasma, the amino acid cysteine and its disulfide cystine are much more abundant than the glutathione system and provide an additional indicator of the balance of pro-oxidant and antioxidant systems. The cysteine/cystine balance in human plasma has been correlated with oxidative stress in aging, cigarette smoking, and cardiovascular disease. Although no consensus exists on ways to measure the damage from oxidative stress, measurement of isoprostanes, the free radical

products of lipid oxidation found in the urine, by mass spectrometry is becoming a standardized and more generally accepted procedure. For the measurement of damage from reactive nitrogen species, the mass spectrometry measurement of nitrotyrosine in plasma proteins is being used as well.

Reductive Stress

In analogy to hyperoxia's being linked to oxidative stress, hypoxia or anoxia may be linked to reductive stress. The term reductive stress was introduced in 1987 by Wendel to denote the metabolic initiation of iron redox cycling following the overproduction of nicotinamide adenine dinucleotide (NADH). From a toxicological point of view, therefore, nicotinamide adenine dinucleotide phosphate (NADPH), or NADH, can be considered to be a detoxicant and a toxicant.

The effects caused by respiratory inhibition (chemical hypoxia), which favors the formation of toxic oxygen species, have been called reductive. The role of vascular endothelial growth factor in mediating the vascular dysfunction induced by hypoxia-like cytosolic metabolic imbalances, such as reductive stress and increased superoxide and nitric oxide production, has been studied. A gene battery responsive to reductive stress has been analyzed.

Nitrosative Stress

While working with nitrosothiols, Hausladen et al. observed a transcriptional activation of the *oxyR* regulon, which they called nitrosative stress. This area, which is of particular interest to vascular physiology and pathophysiology, has been treated in some detail.

Concluding Remarks

It is obvious that the term oxidative stress evokes different associations to researchers coming from different fields of interest. Thus, sometimes it has been overused, and caution is advised when the molecular species are not specified in the transition under study. The various concepts presented here may, in fact, not be at variance with one another; rather, the various terms emphasize a common phenomenon. Likewise, there are many parallelisms between the reactions distinguished as nitrosative versus oxidative. This shows that protection can be afforded against oxidative stress and nitrosative stress simultaneously, underlining the close relationship between the two.

Oxidative Stress and Acidosis

Molecular Responses to Oxidative Stress and Acidosis

Mechanisms Mediating Molecular Responses to Oxidative Stress and Acidosis

Summary

Glossary

<i>Acidosis</i>	An increase in the acidity, and thus a decrease in pH.
<i>Cysteine</i>	An amino acid (subunit of protein) particularly sensitive to oxidation.
<i>Cytochrome B</i>	An essential component of mitochondrial metabolism, which functions in electron transport chain complex III.
<i>Cytochrome oxidase</i>	An essential component of mitochondrial metabolism, which functions to facilitate electron transport.
<i>Free radical</i>	A molecular species such as O_2^- , which by virtue of a free electron is energetically favored to reactively oxidize many compounds and cellular constituents.
<i>Heme oxidase 1</i>	An enzyme that protects cells from oxidative damage.
<i>Metallothionein</i>	A protein that protects cells from oxidative damage.
<i>Mitochondrial rRNAs</i>	Ribosomal RNAs used to translate proteins in the mitochondria.
<i>Oxidation</i>	A chemical reaction in which a compound or molecular constituent loses electrons.
<i>Oxidative state</i>	A reflection of the likelihood that atoms in the environment will gain or lose net electrons or hydrogen atoms; in a more highly oxidative state sulfur atoms in the side chains of the amino acid cysteine will tend to lose net electrons and hydrogen atoms, thus enhancing the production of disulfide bridges.
<i>Oxidative stress</i>	Potentially toxic increase in oxidative state of the cell, leading to characteristic molecular responses.
<i>OxyR protein</i>	A protein that regulates gene expression which, when activated by oxidative stress, stimulates the expression of anti-oxidant genes.

Reduction

A chemical reaction in which a compound or molecular constituent gains electrons.

Superoxide dismutase

An enzyme that protects against oxidative stress by inactivating the highly oxidant free radical O_2^- .

Oxidative Stress and Acidosis

The internal milieu of the cell is highly regulated, and any displacement from this milieu can have fatal consequences. Therefore molecular mechanisms have evolved to counter environmental influences which threaten to disrupt this milieu. These molecular mechanisms entail responses which are common (stereotypic) in a wide range of cells and in response to a wide variety potentially toxic influences. Thus, these molecular responses may usefully be considered to be molecular stress responses. However, these general stress responses are also accompanied by more specific changes which depend on the cell type and specific stressor. Perhaps the best-studied of these molecular stress responses are the heat-shock proteins, which were first observed to be induced by a potentially lethal increase in temperature. The heat-shock proteins are discussed in detail elsewhere in this encyclopedia. As discussed there, the heat-shock proteins are not only induced by elevated temperature, but also by a wide variety other stressors, among which are changes in the oxidative state and the pH of the cell. However, oxidative stress and acidosis also induce other molecular responses which are not prominent responses to heat shock. These other responses are the focus of this present article.

Oxidative state can best be thought of as the relative attraction of electrons to atoms or compounds. Oxygen is one of the strongest attractors of electrons, so it is relatively oxidizing comparing to almost any other atom. In comparison, hydrogen has relatively little attraction for electrons. Thus when hydrogen and oxygen combine to form water, the hydrogen is oxidized by (loses electrons to) oxygen, and, conversely, the oxygen is reduced by (gains electrons from) hydrogen. In a more general sense, it may be said that the atmosphere, consisting of a relatively high level of oxygen due to ongoing photosynthesis, is characterized by a relatively high oxidative state compared, for example, to the internal state of the cell, in which free oxygen is at much lower concentrations. This disparity partly reflects the fact that life originally evolved in

atmospheric conditions which were much less oxidative than exists today. The physiological significance of this disparity is that the proper function of most proteins requires an oxidative state lower than is found in outside the cell. Even within the cell, some compartments, such as the endoplasmic reticulum, require even more highly reduced conditions than other parts of the cell. However, most cells require oxygen to produce energy, and in the course of producing energy molecular species called free radicals are produced which potentially greatly enhance the local oxidative state inside the cell. Furthermore, other cellular functions, such as certain immunological functions, may entail enhanced production of free radicals. When free radicals or oxidative chemicals increase the oxidative state inside the cell, the result can be the oxidation of proteins, especially at disulfide bonds that are highly sensitive to oxidative status. Because such an increase in oxidative state may be toxic and induces a common set of molecular responses, this change is called oxidative stress. In principle cellular function could also become impaired if oxidative state becomes too low (that is, the internal milieu could be too reduced), but this circumstance rarely occurs in most cells and is not further considered in this article.

In addition to the highly regulated oxidative state, the acidity, or pH, inside the cell is also highly regulated. Acidity, which reflects the concentration of free hydrogen ions, is critically important because the ionic status of most amino acid side chains in proteins is dependent on pH. Therefore, agents that alter internal pH can, like agents that alter oxidative status, also be toxic, and thus not surprisingly cellular responses to acidosis have also evolved. Much less is known about these responses, but molecular responses to acidosis and oxidative stress entail induction of some common species.

Molecular Responses to Oxidative Stress and Acidosis

Molecular responses to oxidative stress entail some common responses and some responses that depend on the cell type and nature of the oxidative stressor. For example, as with many potentially toxic insults, oxidative stress may generally entail induction of heat-shock proteins. However, other responses are different from those induced by heat shock. The range of molecular responses to oxidative stress is indicated by comparing three papers that used the differential display technique to assess molecular responses of three different cell types to either hydrogen peroxide or diethylmaleate. Hydrogen peroxide directly increases oxidative state since it is a highly

oxidative molecule, whereas diethylmaleate increases the oxidative state by depleting the reduced form of glutathione. In a Chinese hamster fibroblast cell line, hydrogen peroxide was observed to cause a decrease in a several transcripts derived from mitochondria (including both 16S and 12S mitochondrial rRNAs, nicotinamide adenine dinucleotide (NADH) dehydrogenase subunit 6; ATPase subunit 6; and cytochrome oxidase subunits I and III). In contrast, most nucleus-derived ribonucleic acid (RNA) species were either not influenced or increased, including messenger RNAs (mRNAs) for several growth-inhibiting proteins. In a human lens epithelial cell line, hydrogen peroxide was observed to influence transcripts derived from both mitochondrial and nuclear genomes. The mitochondrial transcripts (including NADH dehydrogenase subunit 4, cytochrome-b, cytochrome oxidase III, and 16S RNA) were decreased. In contrast, all but one of the nucleus-derived transcripts that were regulated (cytokine-inducible nuclear protein, alternative splicing factor 2, and beta-hydroxyisobutyryl-coenzyme A hydrolase) were increased. Among the nucleus-derived transcripts, only glutamine cyclotransferase was decreased. In the human-derived Hela cell line, diethylmaleate was observed to decrease the levels of RNA species derived from mitochondria, whereas nuclear-derived species, including the ribosomal protein 4, c-fos, and previously uncharacterized mRNAs, were induced. Thus the differential display technique, which in effects surveys across all RNA species, clearly indicates that a common response to oxidative stress is a decrease in mitochondrial RNA species and an induction of a small number of nuclear-derived mRNAs. Since oxidative stress would normally be produced by mitochondrial oxidative metabolism, the decrease in mitochondrial species can be understood as a homeostatic response to decrease the production of oxidative stress. This common oxidative stress response, however, is not observed with heat shock. In contrast, other proteins, including antioxidant proteins such as glucose-6-phosphate dehydrogenase (which catalyzes the rate-limiting step in the production of nicotinamide adenine dinucleotide phosphate hydrogen (NADPH), the source of reducing potential for the antioxidant glutathione), catalase, superoxide dismutase, heme oxidase 1, and metallothionein, are induced by many forms of oxidative stress in many cell types. While these gene products may be induced by thermal or other stressors under some circumstances, their induction by oxidative stress is much more robust. Interestingly, other than heat-shock proteins, the most robust reported response to acidosis is also metallothionein. Both metallothionein and heme oxidase 1 probably serve as antioxidants

by sequestering potentially oxidizing metals, but this remains to be established.

The molecular responses to oxidative stress depend on the severity of the stress, in relation to whether the stress is lethal, produces programmed cell death (apoptosis), or is relatively mild and not only allows the cell to survive but become relatively resistant to subsequent cell death. DNA microarray studies suggest that relatively mild oxidative stress produce molecular responses that could lead to apoptosis, but these potentially lethal responses are inhibited, interestingly, by a concomitant reduction in glycolysis. This reduction in glycolysis actually appears to produce a protective effect, in part by inhibiting apoptosis, but through other mechanisms as well. However, if the oxidative stress becomes severe enough, the apoptotic effects overwhelm the blockade produced by glycolysis inhibition. Even more severe oxidative stress produces cell death directly, without apoptosis (necrosis).

Mechanisms Mediating Molecular Responses to Oxidative Stress and Acidosis

In eukaryotic systems, oxidative stress appears to lead to degradation of mitochondrial RNA species through unknown mechanisms. Oxidative stress increases nuclear-derived mRNAs through several mechanisms, including increased transcription and, as for heme oxidase 1, increased mRNA stability. The molecular details of these effects of oxidative stress in eukaryotes is not well-understood. However, oxidative stress responses in prokaryotes have been examined in some detail.

In bacteria, hydrogen peroxide induces about 30–40 proteins, whereas agents which lead to free production induce an approximately 40 additional proteins. Hydrogen peroxide induces gene expression in part by activating the OxyR protein, which activates transcription of about 10 antioxidant proteins including catalase (the enzyme which converts hydrogen peroxide to water), and glutathione reductase. OxyR is normally inactive in the relatively reduced normal cellular milieu, but hydrogen peroxide leads to an oxidation of two cysteine residues on OxyR which activates the protein. Free radical production induces gene expression in part through the oxidation of SoxS, a transcriptional activator which stimulates the transcription of several antioxidant genes including superoxide dismutase and glucose-6-phosphate dehydrogenase. The oxidation of SoxS takes place at an iron–sulfur center, so requires a higher energy form of oxidation than is produced by hydrogen peroxide alone. Thus, molecular responses to different

forms of oxidative stress can be appropriately generated through effector molecules with sensitivities to different forms of oxidation. Recent studies suggest that a similar process occurs in eukaryotes, entailing the activation of the transcription factor Nrf2 via the mitogen-activated protein (MAP) kinase signaling pathway.

Summary

Life initially evolved under conditions of much lower oxygen than is the case at present and most cellular processes therefore require a lower state of oxidation than is found in air. Therefore specific and highly regulated processes have evolved to maintain this lower state of oxygen even in the face of metabolic insults. Several levels of antioxidant defenses exist, to accommodate precise levels of oxidative challenges. Some of these antioxidative proteins, including metallothioneins, are also induced to protect against acidosis.

Reduction

A chemical reaction in which a compound or molecular constituent gains electrons.

Metabolism Drives Aging: The Free Radical Hypothesis
Oxidative Stress Increases with Age
Functional Evidence That Oxidative Stress Limits Life Span

Glossary

<i>Free radical</i>	A molecular species such as O_2^- , which by virtue of a free electron is energetically favored to reactively oxidize many compounds and cellular constituents.
<i>Mitochondria</i>	The powerhouse of the cell, where ATP, the main source of cellular energy, is produced.
<i>Mitochondrial electron transfer chain</i>	A specialized process in the mitochondria whereby electrons are passed down a chain of five complexes, allowing for the production of ATP.
<i>Oxidation</i>	A chemical reaction in which a compound or molecular constituent loses electrons.
<i>Oxidative state</i>	A reflection of the likelihood that atoms in the environment will gain or lose net electrons or hydrogen atoms; in a more highly oxidative state, sulfur atoms in the side chains of the amino acid cysteine tend to lose net electrons and hydrogen atoms, thus enhancing the production of disulfide bridges.
<i>Oxidative stress</i>	The potentially toxic increase in oxidative state of the cell, leading to characteristic molecular responses.

Metabolism Drives Aging: The Free Radical Hypothesis

The causes of aging have been the subject of speculation since before the dawn of recorded history, and in the era of science such speculations have become even more numerous. At present, to the extent that a unitary mechanism of sorts is seriously entertained by gerontologists, the hypothesis that aging is caused by oxidative damage is the most widely accepted. This hypothesis had its origins in the observation that life span seems inversely correlated with metabolic rate, which gave rise, early in the twentieth century, to the rate of living theory. This hypothesis, inspired by the fantastically successful conservation laws of classical physics, hypothesized that the total amount of metabolic activity an individual could sustain over its life span is a constant. This hypothesis accorded well with the basic observation with inanimate objects that use leads to deterioration and with the intuition that, in human life at least, those who live fast, die young; it also accorded well with a more objective analysis that, for example, heart rate is much higher in short-lived mammals than in long-lived mammals. Indeed, this observation gave rise to the hypothesis that the lifetime number of heartbeats, thought to be a proxy of metabolic rate, is conserved. The hypothesis was strengthened by the incontrovertible demonstration that reducing the temperature in

poikilotherms such as flies and nematodes increased life span. Because reducing the temperature *in vitro* reduces the rate of metabolic and chemical reactions, these observations were highly suggestive that metabolic processes drive aging and limit life span.

Nevertheless, precisely which aspects of metabolism limits life span has continued to be elusive. Recent studies have suggested that total metabolic activity is in fact not conserved; for example, caloric restriction can increase life span without producing a concomitant decrease in tissue-specific metabolic rate. In 1956, by analogy with radiation-induced cellular damage, Dennis Harman suggested that the metabolic process that limits life span is the production of free radicals whose main damaging effect is mediated through the oxidation of macromolecules such as protein and DNA. This free-radical hypothesis of aging emphasized the role of oxidative stress, although in principle oxidative stress could occur through other mechanisms in addition to free radicals. This hypothesis has continued to stimulate much research and continues to be among the most attractive mechanisms to mediate the aging process.

Oxidative stress, defined as evidence of a relatively oxidized state of the cell and its constituents, has been implicated in the aging process by several lines of evidence. Originally, this hypothesis was suggested by the observation that radiation, which can certainly produce oxidative stress, can in some ways mimic the aging process, especially in reducing life span and increasing the incidence of tumor burden. On the other hand, it is not certain that oxidative damage necessarily mediates the pathological effects of radiation, and it has been similarly difficult to prove that oxidative stress mediates the pathologies of aging. Nevertheless, evidence implicating oxidative stress as mediating the pathological effects of aging has continued to grow over the last 50 years.

Oxidative Stress Increases with Age

Perhaps the most obvious evidence is that oxidative stress incontrovertibly increases with age. For example total protein oxidation, as indicated by protein carbonyl levels and nitrotyrosine immunoreactivity, increases by approximately 50% in the brain from maturity to old age. Conversely, total protein reduction, as indicated by sulfhydryl groups, decreased with age. For some proteins, such as glyceraldehyde phosphate dehydrogenase, the age-related oxidation has been located at specific cysteine residues, and the oxidation has been shown to account for the robust decrease in specific activity characteristic of many enzymes during aging. Furthermore, protein oxidation in specific brain regions of aged mice has been

shown to correlate with impairments in functions regulated by those specific brain regions. Thus, for example, the oxidation of hippocampal proteins correlates with impairments in memory function, whereas the oxidation of cerebellar proteins correlates with impairments in tasks requiring fine motor coordination. Oxidative damage to DNA similarly increases with age, especially in mitochondrial DNA. In mitochondria, DNA oxidative damage is mainly manifested by characteristic deletions that can entail the loss of several thousand bases and whose occurrences increases robustly with age in many tissues. In nuclei, DNA oxidation is mainly manifest as the modification of specific bases, especially the conversion of guanine to 8-oxoguanine, and specific oxidized bases in the nucleus, which are most likely due to oxidative damage. Finally, the oxidation of lipids, mainly manifest in the form of 4-hydroxynonenal (HNE) and malondialdehyde, also increases with age in several tissues.

The increased oxidative damage that occurs during aging appears to be due primarily to the increased production of reactive oxygen species during aging, although reduced turnover of proteins and lipids may also play a role. Most reactive oxygen species are produced by the mitochondria, especially in electron transport chain complexes I and III. It is not clear why the production of reactive oxygen species increases with age, but in some tissues at least this may be due to a shift toward the greater use of complex I and away from the use of complex II.

Functional Evidence That Oxidative Stress Limits Life Span

Four main lines of evidence suggest that the increase in oxidative damage that occurs during aging plays an important role in determining life span. First, age increases the lethality of oxidative stress, for example in *Caenorhabditis elegans*. Second, dietary restriction, which increases life span, also increases resistance to oxidative stress. Third, genetic modifications that increase life span (e.g., mutations in the insulin-like receptor) also increase resistance to oxidative stress. Fourth, genomewide unbiased screening revealed that the most prominent class of genes whose ablation increases life span are genes coding for mitochondrial electron transport chain complexes I, III, IV, and V. As previously indicated, these complexes, especially I and III, are the major sources of reactive oxygen species in most cells. Notably missing from these screens were genes coding for proteins in mitochondrial electron transport chain complex II. Indeed, it had already been shown by classic genetic screens that mutations in complex II reduced life span rather than

increasing it. The significance of these observations is that reactive oxygen species are produced at much greater levels in complex I than in complex II. Thus, mutations that reduce complex II activity presumably entail elevated compensatory activity of complex I, increasing the production of reactive oxygen species and reducing life span, whereas genetic manipulations that inhibit complex I have the opposite effect. Precisely such a mechanism seems to mediate the age-related pathologies (and reduced life span) caused by Huntington's disease.

A final line of evidence supporting a role for oxidative stress in life span involve studies that genetically manipulate genes coding for the classic anti-oxidative defense enzymes superoxide dismutase and catalase. Although early studies in flies suggested that transgenic overexpression of these genes might increase life span, later studies failed to replicate this effect. Furthermore, in at least one study genetic reduction in superoxide dismutase activity had no effect on life span, even though this manipulation increased oxidative stress as well as tumor burden. Therefore, the effect of manipulating the activity of classic anti-oxidant defenses on life span must be considered an open question. On the other hand, these classic anti-oxidant enzymes are not the sole determinant of oxidative stress, so the best interpretation of the current evidence is that oxidative stress, but not necessarily the classic anti-oxidant enzymes, is a major determinant of age-related pathologies and mortality.

Conclusion

Glossary

Dendrites

Parts of a cell where information is received and processed; thick, specialized processes arising from the cell body (soma) of a nerve cell (neuron). Most inputs to a nerve cell from other nerve cells arrive at the dendrites. However, for many cells, the transfer of information at the dendrites is bidirectional; neurotransmitters and neurohormones secreted from the dendrites can affect the activity of neighboring cells and can also affect the excitability of the afferent nerve endings.

<i>Natriuresis</i>	Sodium excretion in urine. To keep the plasma concentration of sodium stable, the intake of salt in the diet has to be balanced with appropriately regulated excretion. Natriuresis is regulated by a variety of neural and hormonal mechanisms.
<i>Posterior pituitary gland</i>	The site at which oxytocin and vasopressin are secreted into the general circulation; also called the neurohypophysis. The gland contains only the axons and neurosecretory nerve terminals of magnocellular vasopressin and oxytocin cells; the cell bodies are within the hypothalamus.

Oxytocin, a peptide hormone, is synthesized by large (magnocellular) neurons in the supraoptic and paraventricular nuclei of the hypothalamus. The axons of these neurons project to the posterior pituitary gland, where oxytocin is stored in large vesicles within nerve endings and axon swellings. Electrical activity in the cell bodies is propagated down the axons in the form of action potentials, resulting in the secretion of oxytocin, which then enters the circulation. Thus, the concentration of oxytocin in the blood reflects the electrical activity of oxytocin neurons in the hypothalamus. There are also some peripheral sources of oxytocin, but these are likely to play local, autocrine roles and do not make a substantial contribution to concentrations in the circulation.

Effects of Stress on the Milk-Ejection Reflex

Oxytocin is essential for the transfer of milk from mother to infant. The sucking of a baby at a mother's breast activates sensory receptors in and around the nipple, leading to the activation of spinal nerves. These nerves project indirectly to the hypothalamus, leading to the activation of oxytocin neurons and secretion of oxytocin. The oxytocin is carried in the systemic circulation to the mammary gland, where it acts on myoepithelial cells, causing milk to be let down from these cells into the collecting duct of the mammary gland, from which the baby can draw the milk into his or her mouth. Without oxytocin secretion, there is no milk let-down and a suckling baby will go hungry.

This reflex – the milk-ejection reflex – is abrupt and intermittent. In response to suckling, oxytocin is secreted in pulses every few minutes. These pulses are the result of brief, intense, coordinated bursts of electrical activity in the oxytocin cells, separated

by periods of relative electrical quiescence. Although the reflex is normally activated by suckling, it can also be conditioned – and the sight, sound, or smell of a baby can, in some circumstances, elicit milk let-down.

This reflex is very susceptible to disruption by stress. In humans, as in many mammals, a quiet, familiar, and safe environment and a calm state of mind are conducive to the reflex. Indeed, in rats the milk-ejection reflex appears to require that cortical activity be in a state of slow-wave sleep. However, although stress might thus be described as inhibiting the oxytocin-mediated milk-ejection reflex, it does not follow that stress inhibits oxytocin secretion. The pulsatile pattern of oxytocin secretion in response to suckling means that the mammary gland is exposed to very high circulating concentrations of oxytocin – but for only a few seconds at a time. The gland responds only to high concentrations of oxytocin, and continuous exposure to high concentrations soon leads to desensitization, so anything that disrupts the appropriate patterning of oxytocin secretion can block the milk-ejection reflex. The reflex requires a coordinated, abrupt activation of the oxytocin cells, and many stimuli that increase the basal activity of oxytocin cells also impair their ability to display coordinated, abrupt episodes of activation. Hence, perversely, many stimuli that lead to increased concentrations of oxytocin in the blood at the same time block the pulsatile pattern of secretion that is essential for the physiological efficacy of oxytocin at the mammary gland.

Stress and Parturition

Oxytocin plays an important role during parturition in most, if not all, mammals. In all mammals studied, the uterus becomes highly sensitive to oxytocin toward the end of pregnancy, as a result of the increased expression of oxytocin receptors in both the myometrium and endometrium. Oxytocin acts on the myometrium of the pregnant uterus to induce contractions directly and on the endometrium to stimulate the production of prostaglandins, which also induce uterine contractions. During delivery, the stimulation of the cervix initiates the Ferguson reflex, during which large amounts of oxytocin are secreted from the pituitary gland into the circulation and uterine contractions and abdominal compression also contribute to the activation of oxytocin secretion.

In the rat, oxytocin cells behave during parturition in much the same way as during suckling – they display intermittent intense bursts of activity leading to pulsatile secretion of hormone. Again, this pattern is important for the physiological efficacy of

oxytocin, although less so than in the case of the milk-ejection reflex; the uterus is sensitive to lower concentrations of oxytocin in the circulation and is less susceptible to desensitization.

Like many mammals, including the rabbit and the sow, the pregnant rat builds a nest in which to deliver; some other mammals, such as the cat, ewe, and bitch, do not build a nest but instead seek out a sheltered place. Mammals that are normally most active at night tend to give birth during the day, and those most active during the day tend to give birth at night; in women, the peak incidence for delivery is between 3:00 and 4:00 a.m. Thus, labor generally begins at a time when the animal is normally asleep or resting and in a place that offers relative seclusion and apparent safety. Disturbance – the sight or sound of an intruder or physical movement from the place where labor has begun to a new environment – can disrupt parturition markedly. If a mouse or a rat is taken from her nest once birth has started and is placed in an empty glass chamber or if a sow is moved from the farrowing nest that she has made to an empty pen, subsequent deliveries are delayed. In bitches, ferrets, rabbits, and ewes, even the noticed presence of a human observer can result in prolonged labor associated with the inhibition of uterine contractions. In women too, anxiety is associated with prolonged labor, and although this has not been the subject of controlled observations, uterine contractions often decrease temporarily when a woman in labor is moved from home to the hospital or from the labor room to the delivery room.

Thus, the progress of parturition in mammals is very susceptible to disruption by acute stress, and many authors have suggested that this disruption might be a consequence of a disruption of oxytocin secretion. The acute administration of oxytocin antagonists prolongs parturition in the rat, and the pharmacological inhibition of oxytocin secretion, particularly by opioid agonists, leads to a prolongation of parturition that can be reversed by the administration of physiological doses of oxytocin. Thus, if stress impairs the activation of oxytocin neurons in parturition, then this would be likely to impair the progress of parturition.

When a rat is moved in mid-parturition from her nesting cage to an empty glass bowl, the oxytocin concentrations in the blood fall, but whether this is a primary consequence of stress or is secondary to reduced uterine activity is not clear. In the rat and in the sow, after the administration of the opioid antagonist naloxone, parturition progresses normally despite environmental disturbance, suggesting that stress might activate endogenous opioid pathways

that inhibit oxytocin secretion; oxytocin neurons are known to be very sensitive to inhibition by exogenous opioids. However, in the rat, naloxone administered during parturition potentiates oxytocin secretion even in the absence of overt stress, so it is possible that the normal progress of parturition in the naloxone-treated disturbed rat merely reflects the ability of hypersecretion of oxytocin to overcome the influence of mild stress.

Thus, mild stress can subvert the physiological actions of oxytocin, preventing milk let-down in response to suckling and prolonging parturition. In lactation, stress disrupts the pattern of oxytocin secretion, preventing the coordinated intermittent burst discharge of oxytocin cells that is necessary for pulsatile oxytocin secretion. During parturition, it is less clear how stress interferes with the progress of labor, but it seems plausible that a similar disruption of the patterning of oxytocin secretion leads to a less effective hormonal signal at the uterus. In the case of the milk-ejection reflex, the disruption of the appropriate patterning of secretion might be accompanied by (and might even be caused by) an increased but uncoordinated activation of the oxytocin cells, giving rise to higher average concentrations of oxytocin in the circulation.

Stress-Induced Stimulation of Oxytocin Secretion

In the rat, on which most studies have been performed, most acute stressors that have been tested markedly increase oxytocin secretion from the pituitary gland. Plasma concentrations of oxytocin are increased, for instance, following forcible restraint, noxious stimuli, cold exposure, forced swimming, aversive foot shocks, administration of nausea-inducing agents, and ether inhalation. At least some of the neural pathways that are involved are also involved in mediating the release of corticotropin releasing hormone (CRH) and hence the secretion of adrenocorticotrophic hormone (ACTH). However, stressors described as emotional only, such as social defeat, do not induce oxytocin secretion. Oxytocin secretion also depends on the species; plasma concentrations of oxytocin do not change in humans exposed to stress or in horses exposed to a novel environment. Stress-induced oxytocin secretion in rats is partly mediated by A2 and A1 noradrenergic cells of the brain stem because the oxytocin response to fear-related stimuli or noxious stimuli, for instance, is impaired after central norepinephrine depletion by neurotoxin treatment or by central injection of an α_1 -adrenergic antagonist. However, not all stressors are mediated by

noradrenergic pathways; for example, the disruption of noradrenergic pathways does not affect oxytocin secretion in rats exposed to a novel environment.

These observations raise several questions. Is the stress-induced secretion of oxytocin into the circulation of any physiological significance? Or is it an epiphenomenon, reflecting a disruption of the normal pattern of activity in oxytocin cells that is essential for reflex milk ejection? The disruption of the milk-ejection reflex is undoubtedly a common consequence of stress. Does this disruption have any adaptive benefits, or does it reflect pathological malfunction?

In fact, much less oxytocin is secreted in response to stress in lactating rats than in virgin rats. This might reflect a general hyporesponsiveness to stress during lactation because ACTH secretion in response to many stresses is also reduced. At least in part, the reduced secretion of oxytocin in lactation reflects depleted stores of oxytocin at the posterior pituitary gland because the amount of oxytocin that is secreted in response to a given activation of hypothalamic neurons is proportional to the amount of oxytocin stored in the neurosecretory nerve endings; in lactation, large amounts of oxytocin are secreted in pulses in response to suckling, and the stores are thus normally 40% or more below the levels in virgin rats. However, the pituitary stores of oxytocin increase through pregnancy, so the reduced oxytocin secretory responses to stress seen in pregnant rats requires a different explanation. The hyporesponsiveness of pregnancy seems to suggest that a specific mechanism is activated to reduce the impact of stressors on oxytocin secretion. This might be part of the mechanisms that allow pituitary stores of oxytocin to accumulate during pregnancy, or it might be part of a generalized hyporesponsiveness of stress-related signaling that is reflected by a depression of hypothalamic-pituitary-adrenal (HPA) axis responsiveness to stressors.

Much effort has been expended attempting to find some physiological rationale for the stress-induced secretion of oxytocin. These efforts have addressed three possibilities:

1. Oxytocin secreted in response to stress acts at other targets in the periphery, where its actions are appropriate and adaptive.
2. Oxytocin secreted in response to stress participates in the regulation of ACTH secretion from the anterior pituitary gland
3. The activation of oxytocin neurons by stress releases oxytocin within the brain as well as from the pituitary gland, and this release within the brain mediates the appropriate adaptive responses to stress.

Possible Peripheral Targets for Oxytocin Released during Stress

From this, it should be clear that neither the uterus nor the mammary gland seems a promising candidate as the physiological target of oxytocin that is secreted during stress. However, receptors for oxytocin are also expressed at other peripheral sites, including the heart, the thymus, and, in the rat, the kidney. Although stress induces oxytocin secretion, it is not clear which peripheral target oxytocin acts on or what its physiological effect is.

At the rat kidney, oxytocin promotes natriuresis; this provides an apparent explanation for the elevated secretion of oxytocin observed in response to increased plasma osmotic pressure. In the rat, oxytocin is also secreted in response to gastric distention, possibly indicating that it mediates a reflex natriuresis following food intake. Similar secretion of oxytocin can be evoked by peripheral injections of cholecystokinin; cholecystokinin is a gut peptide released during feeding and acts on afferent gastric vagus nerve endings. It is difficult to envisage any adaptive value to reflex natriuresis in response to generalized stress, but it seems possible that the activation of this pathway is an incidental consequence of vagal activation. This pathway seems to be a characteristic of the rat; in humans, cholecystokinin increases the secretion of vasopressin but not oxytocin.

In the rat heart, oxytocin receptors are expressed in atrial myocytes, and oxytocin acting at these receptors might participate in the release of atrial natriuretic peptide (ANP). Despite its name, the major physiological role of ANP is probably not to regulate natriuresis, although this is one of its actions; instead, ANP appears to regulate the rate and force of cardiac contractions. The actions of oxytocin reduce blood pressure and reduce cardiac output – not an obviously helpful response to an acute stress, but it might be protective against excessive cardiovascular effects of sympathoadrenal activation. These actions of oxytocin seem more consistent with a role for oxytocin in body-fluid homeostasis through coordinated actions at the heart and kidney.

The thymus is responsible for the selection of the peripheral T-cell repertoire. Oxytocin, like many neuropeptides, has been identified in the human thymus by immunoreactivity and at the transcriptional level; it is present in the thymus in surprisingly large amounts in subtypes of thymic epithelial cells. Oxytocin is co-localized with the cytokeratin network of thymic epithelial cells rather than in secretory granules, so it is not secreted, but behaves like an antigen presented at the cell surface. Thymic oxytocin

also behaves as a cryptocrine signal, interacting with receptors expressed by pre-T cells. Oxytocin receptors are expressed by cytotoxic CD8⁺ lymphocytes, and oxytocin induces phosphorylation of focal adhesion kinase in pre-T cells. Thus oxytocin might intervene in T-cell differentiation as a neuroendocrine self-antigen and as a promoter of T-cell focal adhesion. There is little evidence that circulating oxytocin has important effects at this site, and the possible adaptive value of actions of circulating oxytocin at the thymus is unclear. No convincing case has been made so far that oxytocin secreted into the peripheral circulation in response to stress has any adaptive physiological consequences at the thymus, but there has been very little investigation of this possibility.

Possible Actions of Oxytocin at the Anterior Pituitary Gland

The secretion of oxytocin in response to acute stress has prompted speculation that it might play a role in regulating ACTH secretion from the anterior pituitary gland, and pharmacological studies have indicated that oxytocin can indeed induce ACTH secretion from dispersed rat anterior pituitary cells in synergy with CRH. The ACTH-secreting activity is apparently not mediated by oxytocin receptors because oxytocin receptor mRNA is not expressed in corticotrophs and because specific oxytocin agonists have little effect on ACTH secretion; this effect might be mediated by vasopressin receptors because it can be inhibited by a vasopressin V₁ receptor antagonist. The action of oxytocin on corticotrophs suggested by *in vitro* studies has yet to be confirmed to be physiologically relevant *in vivo* in conditions of stress.

ACTH is secreted in response to the synergistic releasing activities of CRH and vasopressin; these two peptides are co-expressed in parvocellular neurosecretory neurons of the paraventricular nucleus that project to the median eminence, where these peptides are released into the hypothalamic-hypophyseal portal circulation. Oxytocin secreted from the posterior pituitary gland does not appear to have direct access to the anterior pituitary gland because few blood vessels connect the separate lobes of the pituitary gland. However, some collaterals of the axons of magnocellular neurons might terminate in the median eminence, and there are also separate parvocellular populations of oxytocin neurons in the paraventricular nucleus, some of which project to the median eminence. Physiological circumstances associated with elevated secretion of oxytocin into the circulation are not consistently associated with high rates of secretion of ACTH, but the conjunction of high CRH release with high oxytocin secretion might lead to a potentiation of ACTH secretion under some

circumstances because oxytocin at high concentrations is capable of triggering ACTH secretion from corticotrophs and oxytocin appears to act synergistically with CRH. It is not clear whether these actions of oxytocin are physiological rather than purely pharmacological; oxytocin receptors appear to be expressed at relatively low levels in the anterior pituitary gland, but oxytocin at high concentrations can also act at vasopressin receptors and vasopressin receptors on corticotrophs mediate the synergistic ACTH-releasing effects of vasopressin co-secreted with CRH.

A fully convincing case has yet to be made that oxytocin, released either from magnocellular neurosecretory neurons into the circulation or from parvocellular oxytocin neurons projecting to the median eminence, is important for the physiological regulation of ACTH secretion at the level of the pituitary gland, but oxytocin released centrally does appear to be involved in regulating HPA axis activity.

Oxytocin Release within the Brain

Oxytocin does not cross the blood-brain barrier in significant quantities, and oxytocin receptors do not appear to be prominently expressed at brain sites that lack an effective blood-brain barrier. Thus, oxytocin secreted from the posterior pituitary gland into the systemic circulation does not act in the brain. However, oxytocin is present at high concentrations in the cerebrospinal fluid (CSF) and at a number of sites within the brain; this oxytocin does not derive from the blood but from oxytocin released within the brain. A lot of oxytocin is released from the soma and dendrites of magnocellular neurosecretory neurons; this release, within the supraoptic and paraventricular nuclei, generally accompanies the electrical activation of the magnocellular oxytocin cells. However, there are differences in the time course of oxytocin release centrally and peripherally, and different stimuli have differential effects on the central and peripheral release of oxytocin; these observations suggest that there are important differences in the regulation of dendritic oxytocin release and release from nerve terminals. In the rat supraoptic and paraventricular nuclei, forced swimming, shaker stress, and social defeat all induce dendritic release of oxytocin from magnocellular neurons. The role for dendritic oxytocin during stress is unclear, but endogenous oxytocin modulates the activity of supraoptic oxytocin cells and their noradrenergic inputs in response to noxious stimuli.

Many stressors induce the central release of oxytocin, producing very high extracellular concentrations in several regions of the brain including the hypothalamus (especially the supraoptic and paraventricular

nuclei), the septum, and the amygdala. Central oxytocin is thought to be an antistress and anti-anxiety factor; in rats, the central injection of an oxytocin antagonist increases basal plasma concentrations of ACTH and facilitates ACTH secretion in response to various stressors and the central injection of oxytocin attenuates glucocorticoid secretion in response to stress. Rats previously exposed to the central or peripheral administration of oxytocin are less anxious when challenged in an elevated-plus maze, a behavioral test of anxiety. Central oxytocin also attenuates stress-induced CRH mRNA expression in the paraventricular nucleus and attenuates the expression of *c-fos* mRNA in stress-activated neural circuits, including the paraventricular nucleus, the septum, and the hippocampus.

The significance of the presence of oxytocin in the CSF is not clear. Although it has been speculated that the CSF might be a medium for disseminating oxytocin, mediating brain hormone-like actions, it might be that the CSF is simply a sewer, clearing oxytocin from its localized sites of activity.

The oxytocin neurons that project centrally are mainly located in the paraventricular nucleus. There are several functionally and anatomically distinct populations of parvocellular oxytocin cells in this nucleus. One population projects to the brain stem and appears to be implicated in gastric reflexes; these neurons, like magnocellular oxytocin neurons, are activated following systemic injections of cholecystokinin, and they might be part of a reflex loop that regulates gastric motility. Another population projects to the spinal cord and, in males, appears to be involved in penile erection. Oxytocin-containing fibers are also present in many other brain areas, including the preoptic area, the ventromedial nucleus of the hypothalamus, the bed nucleus of the stria terminalis, and the hippocampus. The origin of these diffusely scattered fibers is generally thought to be a separate population or populations of parvocellular oxytocin neurons in the paraventricular nucleus, whose functions are largely unknown.

Experiments involving central injections of oxytocin or of oxytocin antagonists have led to suggestions that oxytocin influences many functions and behaviors. The strongest evidence concerns ingestive behaviors (central oxytocin inhibits food intake and sodium appetite) and reproductive behaviors. Centrally acting oxytocin has been implicated in sexual behavior in both male and female rats, in the initiation of maternal behavior after parturition in the rat, and in pair bonding, notably in the prairie vole. The central release of oxytocin is undoubtedly involved in the milk-ejection reflex: intracerebroventricular injections of 1 ng oxytocin in a lactating rat lead

to a striking increase in the frequency of suckling-induced milk ejections over the following 30 min, whereas intracerebroventricular injections of selective oxytocin antagonists block this reflex. These effects probably reflect the dendritic release of oxytocin from magnocellular neurons that occurs in response to suckling. Intracerebroventricular injections of much larger amounts of oxytocin (1 μ g) have many consequences – including an increased activity of the HPA axis and of the sympathoadrenal system. Such doses greatly exceed the total oxytocin content of the brain and, indeed, are close to the total amount of oxytocin stored in the pituitary gland. It is not clear where in the brain the administered oxytocin acts to produce these effects, that these effects are all mediated by specific oxytocin receptors, or that they mirror any physiological role of endogenous oxytocin. Daily repeated intracerebroventricular injections of high doses of oxytocin produce contrasting effects, including lowered blood pressure, behavioral calm, and lowered activity of the HPA axis.

Suckling itself has a calming influence on the mother and, indeed as mentioned previously, the state of slow-wave sleep observed in rats to be a prerequisite for the milk-ejection reflex might be facilitated by suckling. Whether endogenous oxytocin is involved in this is not clear.

Thus, although centrally projecting oxytocin cells are activated by a variety of stresses, there is no convincing evidence yet that this activation plays any useful or adaptive role or has any important consequences. However, oxytocin is involved in a wide range of behaviors, particularly reproductive behaviors and social behaviors, that are strongly influenced by stressors. Although it has been generally assumed that the source of the oxytocin that is involved in behaviors is the centrally projecting parvocellular oxytocin neurons, there is growing evidence that oxytocin release from the dendrites of magnocellular oxytocin neurons might be important in many behaviors, including behaviors related to stress. In the final section, therefore, we indicate the key experimental evidence that has led to a current focus of attention on dendritic oxytocin release.

Dendritic Oxytocin Release and Priming

The dendrites of magnocellular neurons are large processes, packed with neurosecretory vesicles that contain oxytocin or vasopressin, and they form a dense plexus at the ventral surface of the brain below the supraoptic nucleus. We now know that the dendrites of many different neurons are electrically active, they can conduct action potentials, and they can release many neuroactive substances. Probably only the classical prejudice that dendrites are not

electrically active but are merely passive receivers of information caused us to be slow to recognize the ventral dendritic plexus of the supraoptic nucleus for what we now know it to be – a neurosecretory gland within the brain itself that is the source of very high release levels of oxytocin and vasopressin that can then diffuse to act at distant sites within the brain.

Stimuli that result in oxytocin secretion from the pituitary gland generally also result in dendritic oxytocin release, but in many circumstances dendritic release is very delayed compared to peripheral secretion, although in a few circumstances central release can precede systemic secretion. The regulation of peripheral secretion is now very well characterized – all secretion from this site is thought to be regulated by action potential activity, depolarization of neurosecretory terminals in the pituitary gland result in calcium entry into the terminals via voltage-gated calcium channels, and this calcium entry is the key step in triggering exocytosis of the large neurosecretory vesicles in which oxytocin is packaged. However, secretion from the dendrites is not all activity-dependent in the same way. Some agents, such as the peptide α -melanocyte-stimulating hormone (α -MSH), can trigger dendritic secretion even though they cause no increase at all in the action potential activity of oxytocin cells; on the contrary, α -MSH inhibits the electrical activity of oxytocin cells and thus depresses the secretion of oxytocin into the blood. α -MSH-induced oxytocin release from dendrites appears to be the result of calcium mobilization from intracellular stores rather than the result of calcium entry into the cell through membrane channels, and other peptides, including oxytocin itself, can act similarly.

Interestingly some agents that mobilize intracellular calcium stores also induce an important change in the behavior of oxytocin cells, called priming. In addition to directly causing dendritic oxytocin release, these agents also prime a readily releasable pool of oxytocin, making it available for subsequent activity-dependent release. Thus it appears that the dendrites might contain two functional pools of neurosecretory vesicles, a readily releasable pool that is available for release in response to depolarization-induced calcium entry, as at the neurosecretory terminals, and a much larger pool of vesicles that are not released in response to action potential activity but can be released by agents that mobilize calcium from intracellular stores. Such agents can augment the readily releasable pool, making more oxytocin available for subsequent activity-dependent release, and can thus exert complex and very long-lasting effects on oxytocin cell behavior.

Oxytocin neurons express oxytocin receptors; oxytocin released from dendrites acts back on oxytocin

cells to modulate their activity, including by priming activity-dependent oxytocin release, and this local feedback plays an important part in the patterning of discharge of oxytocin cells. Whether oxytocin has physiological actions on other neurons in the supraoptic or paraventricular nuclei has not been established yet; but it does not act directly on magnocellular vasopressin cells. The dendritic release of oxytocin is very substantial, and spillover of this release into the CSF probably accounts for some of the oxytocin detected there. However, other populations of oxytocin cells in the paraventricular nucleus project centrally, and these other sources probably also contribute to oxytocin concentrations in the CSF.

Conclusion

In the rat, the release of oxytocin both peripherally and centrally is influenced profoundly by stress. Stresses generally increase oxytocin secretion in the rat, but they disrupt the normal pattern of secretion, leading to a hormonal message that is less effective. Thus, the interruption of milk let-down and parturition that accompanies mild stress might be physiologically appropriate; the enhanced secretion of oxytocin *per se* has no clearly established benefit. However, there is currently speculation, based mainly on behavioral effects seen after the central administration of high doses of oxytocin, that the central release of oxytocin has a generally calming influence.

Introduction

Stress-Induced Analgesia

Stress-Induced Hyperalgesia

Glossary

<i>Analgesia</i>	A decreased perception of pain.
<i>Hyperalgesia</i>	An increased perception of pain.
<i>Nociception</i>	A perception of pain.
<i>Opioid</i>	Any of three families of endogenous peptides (i.e., as endorphin, enkephalin, and dynorphin) that induce analgesia by binding to μ , δ , or κ opioid receptors.

Introduction

Definition and Measurement of Pain

Pain has been defined as an aversive sensation originating from a noxious stimulus in a defined area of the body. Such intense, potentially tissue-injurious stimuli activate nociceptive sensory neurons (nociceptors), which transmit signals via the spinal cord to the brain that are perceived by the organism as pain. The central nociceptive processing areas include the thalamus, hypothalamus, mesencephalic tegmental area, mesolimbic areas, parabrachial nuclei, amygdala, bulbopontine reticular formation, and the somatosensory cortex. Pain has two components: a sensory or discriminate component and an affective or emotional component. Because pain involves both of these components, simply recording from peripheral nociceptors does not provide a sufficient measurement of pain because the affective component of pain is not

assessed in this manner. To circumvent this problem, behavioral measures of pain are used. If animals display characteristic behaviors after application of a noxious stimulus, including withdrawal of the area to which the stimulus is applied, licking of the affected area, vocalization, or escape behavior, it is inferred that the animal is experiencing pain. A commonly used behavioral test for the measurement of pain in animals and the test upon which much of the current information on stress effects on pain is based is the tail flick test. In this test, an animal is lightly restrained and its tail is exposed to a heat source intense enough to produce pain in humans. The time it takes for the animal to remove its tail from the heat source is recorded as tail flick latency; the more painful the stimulus, the shorter the latency. An additional tool used to identify pain is the administration of opioid analgesics such as morphine. Morphine activates an endogenous pain control circuit to block the transmission of nociceptive signals. Therefore, if a noxious stimulus-induced behavior is blocked by morphine, it is considered to be painful.

Definition and Measurement of Stress

Stress is generally defined as any stimulus to which the organism is not adapted. Like pain, stress involves a perceptual component and is therefore difficult to assess in laboratory animals. To circumvent this problem, hormonal measurements are commonly used. Stressful stimuli activate three neuroendocrine circuits: the hypothalamic-pituitary-adrenocortical (HPA) axis, the sympathoadrenal axis, and the sympathetic neural axis. Although different stressors may activate these axes to varying degrees, all axes are activated by most stressful stimuli. Therefore, the hormonal measurement of activation of one of these axes, generally the HPA axis, is used as an operational definition of stress. Both adrenocorticotrophic hormone (ACTH) and corticosterone are secreted rapidly into the blood upon activation of the HPA axis. Stimuli that evoke increases beyond normal circadian

levels in either of these hormones are considered stressful.

How do these broad, somewhat overlapping concepts, pain and stress, relate to each other? One of the first written observations of the relationship between pain and stress comes from observations made by field doctors in Europe during World War II. These doctors observed that up to 70% of soldiers presenting with severe battle wounds would not report significant levels of pain. This apparent insensitivity to pain was short-lived; 24 h later, all soldiers reported significant levels of pain. Reports such as these suggested that the perception of pain could be modified cognitively. Because stress seemed to be a common factor in all of these reports, the question arose as to whether stress could affect pain perception. In 1976, a decreased perception of pain after exposure to a stressor was shown in laboratory experiments for the first time and was termed stress-induced analgesia. Although less well studied, it has also been shown that stress can enhance pain perception in some circumstances. This phenomenon has been termed stress hyperalgesia and is generally referred to as stress-induced hyperalgesia.

Stress-Induced Analgesia

Stress-induced analgesia refers to the well-established phenomenon that exposing humans or animals to a wide variety of stressors induces the suppression of pain perception. Although electric foot shock and cold water swim have been the most well-studied eliciting stressors, others include rotation, immobilization, and food deprivation. The decrease in pain sensitivity in these studies is usually measured as an increase in tail flick latency to noxious thermal stimuli. However, other pain sensitivity tests such as paw withdrawal, paw licking, and escape behavior in response to exposure to electrified grids or hot plates are also used.

Although the mechanisms of stress-induced analgesia are not completely understood, two subtypes of stress-induced analgesia – endogenous opioid dependent (opioid mediated) and opioid independent (nonopioid mediated) – can be distinguished. Opioid-mediated stress-induced analgesia is defined as stress-induced analgesia that either is blocked by the opiate receptor antagonist naloxone or is cross-tolerant to opioid agonists such as morphine. Cross-tolerance is determined by treating an animal for several days with morphine until the drug no longer produces analgesia. A stressful stimulus is then applied, and if the analgesia is blocked, then it is considered cross-tolerant to morphine. The nonopioid-mediated type of stress-induced

analgesia is unaffected by these treatments. Characteristics of the stressor, including the temporal pattern of administration and severity, seem to predict whether opioid or nonopioid analgesia will be induced. In general, stressors that are intermittent and less severe produce opioid-mediated analgesia, whereas stressors that are continuous and of greater severity produce nonopioid-mediated analgesia. Both forms can be classically conditioned.

The distinct nature of opioid- and nonopioid-mediated subtypes of stress-induced analgesia is supported by the fact that they are not cross-tolerant. In fact, a collateral inhibition model has been proposed by Bodnar and colleagues in which activation of one form of stress-induced analgesia would actively inhibit the other form. These investigators have shown that, if administered closely in time, non-opioid-mediated analgesia inhibits opioid-mediated analgesia. This is in contrast to the well-established phenomenon that distinct elicitors of opioid-mediated stress-induced analgesia synergize to produce greater analgesia. Bodnar and colleagues propose that collateral inhibition allows the animal to use its most adaptive system in response to potentially widely varying stressful situations presented by the environment.

The mechanism of opioid-mediated stress-induced analgesia is thought to involve both central and peripheral sources of opioids as well as both central and peripheral sites of action. Stress activates endogenous opioidergic neural circuits in the midbrain, which then transmit signals through the dorsolateral funiculus to inhibit pain transmission circuits in the dorsal horn of the spinal cord. Stress also induces the release of opioids from peripheral sources, including the pituitary gland and the adrenal medulla, and, during inflammation, from leukocytes. These opioids may act by binding to receptors on terminals of nociceptive peripheral sensory nerves and inhibiting noxious stimulation-induced activation or sensitization of these neurons. It is important to note that while these opioidergic pathways are a key element in mediating this type of analgesia, other neurotransmitters (e.g., serotonin, norepinephrine, acetylcholine), neuropeptides (e.g., cholecystokinin), and hormones (e.g., corticosterone) may also participate in this pathway.

Although it is clear that distinct pathways mediate opioid and nonopioid forms of stress-induced analgesia, there is some evidence that there may also be some pathways in common. Similar to opioid-mediated forms of stress-induced analgesia, both midbrain structures and the dorsolateral funiculus of the spinal cord are involved in mediating nonopioid stress-induced forms of analgesia. Additionally, mouse strains have been developed that express high or low levels of

stress-induced analgesia. This phenotype is present whether the animals are exposed to stressors that characteristically induce opioid- or nonopioid-mediated analgesia. However, in the absence of specific gene products, this is not strong evidence for an overlap in the mechanism but does offer a promising avenue for future studies. In contrast to opioid-mediated stress-induced analgesia, vasopressin, thyrotropin-releasing hormone, and histaminergic systems are involved in mediating nonopioid-mediated stress-induced analgesia. Some forms of nonopioid-mediated stress-induced analgesia (e.g., continuous cold water swim) are mediated by the HPA axis and, in particular, by the adrenocortical system, whereas other forms (e.g., continuous foot shock of short duration) are not. Additionally, dopaminergic and cholinergic systems may play a role in mediating continuous cold water swim analgesia. Clearly, further research is required to elucidate the pathways that mediate nonopioid-mediated stress-induced analgesia.

Stress-Induced Hyperalgesia

Stress-induced hyperalgesia is defined as an increased sensitivity to noxious stimuli or a decrease in analgesia after exposure to stress. In the laboratory, an increased sensitivity to noxious stimuli is usually indicated by a decreased tail flick latency to noxious heat stimulation. Stress-induced hyperalgesia has been observed in animals after exposure to a variety of stressors, including ether, mechanical oscillation, vibration, a novel environment, and repeated exposure to cold temperatures. Stress-induced hyperalgesia has been much less well studied than stress-induced analgesia, and consequently the mechanisms of stress-induced hyperalgesia are still poorly understood. However, a general concept is emerging that an induction of stress-induced hyperalgesia is due to changes in the central, possibly perceptual, processing of nociceptive information by the organism and not due to changes in the processing of noxious stimuli at the level of the peripheral nociceptive pathways as may contribute to stress-induced analgesia. This emerging concept is based on several lines of evidence. First, electrophysiological recordings from nociceptive sensory neurons in the peripheral nerves indicate no change in sensitivity to the noxious stimulus before and after stress-induced hyperalgesia is elicited. Second, stress-induced hyperalgesia can be classically conditioned such that even when a noxious stimulus is not applied, a neutral stimulus that had been paired previously with the noxious stimulus can elicit hyperalgesia. Third, emotional characteristics of the rat can determine whether

stress-induced hyperalgesia is induced. Although it is difficult to assess the emotional state of a rat, studies have shown that rats displaying behaviors thought to indicate anxiety (e.g., vocalization, agitation) during exposure to stress and the noxious stimulus display stress-induced hyperalgesia, whereas rats not displaying these behaviors and exposed to identical stimuli do not show stress-induced hyperalgesia. This concept is supported by the fact that administering antianxiety drugs (e.g., clonidine, diazepam) to these rats blocks stress-induced hyperalgesia, whereas administering anxiety-producing drugs (e.g., yohimbine) enhances and prolongs stress-induced hyperalgesia. Finally, clinical studies indicate that anxious patients display an increased sensitivity to pain. Of course, in these studies it is difficult to assess whether patients are more sensitive to pain because they are anxious or whether they are anxious because they are perceiving more pain. Further investigation will be required to elucidate the factors that elicit and the mechanisms that produce stress-induced hyperalgesia. Additionally, it has been shown that stress may inhibit the analgesic effects of drugs as well as enhance pain perception; however, the relationship between these two effects is currently unknown. Further investigation will be required to distinguish these two phenomena.

Glossary

<i>Panic attacks</i> (PA)	The name used currently for unexpected attacks of fear.
<i>Panic disorder</i> (PD)	Originates from the Greek god of flocks, Pan, who would frighten animals and humans out of the blue.
<i>Spontaneous panic attacks</i>	The main characteristic of PD that is central to its recognition and diagnosis.

Symptoms

One of the main characteristics of panic disorder (PD) is spontaneous out of the blue panic attacks (PAs). PAs usually occur immediately upon exposure or in anticipation of exposure to particular situations, often ones in which panic attacks have previously occurred.

Symptoms of PAs in order of their frequency are palpitations, pounding heart, tachycardia, sweating, trembling or shaking, shortness of breath or smothering, feeling of choking, chest pain or discomfort, nausea or abdominal distress, feeling dizzy, unsteady, lightheaded or faint, derealization or depersonalization, fear of losing control or going crazy, fear of dying, chills, and hot flashes.

Panic attacks usually last for several minutes, but they can also last for hours. In one of the largest modern PD clinical trials, patients averaged one to two PAs per week. However, the frequency and severity of PAs vary greatly between individuals and, at times, in individuals. Some may have only one to three PAs per year, whereas others may have multiple PAs on a daily basis. Some individuals will even have bursts of PAs and then not experience attacks for a long period of time.

Because PAs are extremely frightening, patients will often develop a logical fear that they will reoccur. This anticipatory anxiety increases prior to exposure to situations in which patients have experienced previous PAs. Because of this, PD patients often develop

agoraphobia, which is avoidance of certain places or situations. Agoraphobics often avoid situations in which they have had PAs because they are afraid that escape would be difficult or embarrassing or that help might not be available during these attacks. In community samples, one-third to one-half of patients who meet criteria for PD also have significant agoraphobia avoidance.

There are typical situations that are avoided most frequently. These include taking buses, trains, or planes; riding in or driving a car; being in large crowds; standing in lines; shopping; and being in spaces where they might feel trapped (e.g., bridges, tunnels, elevators). Patients experiencing a PA will often have an overwhelming need to escape or return to a place of safety, like home. These patients do not actually fear the situation itself but are afraid of the feelings of panic that might happen while in that situation.

Many patients even have PAs that begin during sleep. These nocturnal panic attacks are quite common, and the majority of PD patients experience them. These PAs occur during the beginning states of the sleep cycle and are essentially identical to daytime PAs.

There also is a close relationship between depression and PD. In various samples, comorbid or secondary depression ranged from 22 to 68%. Proper recognition of comorbid depression is especially important because of the marked increase in suicide attempts (23.6–50%) in patients with both PD and depression.

Diagnosis

The diagnosis of PD has several requirements.

1. Recurrent, unexpected PAs (situational PAs could also occur, but there would need to be at least two unexpected PAs by history).
2. Panic attacks need to be followed by at least 1 month of (1) persistent anxiety about the potential recurrence of further PAs, (2) persistent anxiety about the implications of these attacks (e.g., going crazy, something wrong medically), or (3) a significant behavioral change because of these attacks.

PD in the General Medical Setting

There is poor recognition of PD in the general medical setting. It is often undiagnosed, because physical symptoms of PD can be mistakenly linked to other medical conditions. However, panic-like symptoms can occur in a few medical conditions (e.g., hyperthyroidism, pheochromocytoma, seizures, cardiac arrhythmias, and chronic obstructive pulmonary disease).

Conservative estimates of PD in primary care have ranged from 3 to 8%, with at least 50% of patients with PD being unrecognized. The average length of time for a patient in the general medicine setting to be diagnosed correctly with PD is 10 years, with an escalation of the use of health-care services over this 10-year period. Overall, PD patients are three times more likely to utilize general medical services than the traditional patient in a primary care setting. The percentage of PD patients is also markedly higher in certain medical groups (e.g., cardiology and gastroenterology).

A study sponsored by the World Health Organization (WHO) studied primary care patients in 14 different countries. Ninety-nine percent of patients with one PA in the previous month had an anxiety disorder or depression or a subthreshold anxiety disorder or depressive disorder. If replicated, it would appear that the occurrence of even a single PA should serve as a signal for increased scrutiny for anxiety and depressive syndromes.

Epidemiology

There is a striking uniformity worldwide for the observed prevalence of PD, generally averaging between 1 and 2% in multiple studies. In the WHO Primary Care Survey of 14 countries mentioned previously, the prevalence for PD ranged from a low of 1.4% to a high of 16.5% for PAs and 0–03.5% for PD itself. The average for PD was 1.1% (current) and 3.5% (lifetime), which was similar to community samples. As mentioned, rates are much higher in certain medical settings, ranging from 15% in dizziness clinics to 16–65% in cardiology practices and 35% in hyperventilation clinics.

Risk Factors

In treatment samples, PD has been observed to be at least two times more prevalent in females than in males. Males tend to have a longer duration of illness but are less likely to seek help or develop agoraphobia and depression. The onset of PD for both genders usually occurs between 15 and 24 years of age, with a second peak at 45–54 years of age. The onset of PD after the age of 65 is rare (0.1%).

As mentioned previously, agoraphobia is also more prevalent in females, with the highest rates of PD and agoraphobia occurring in widowed, divorced, or separated individuals living in cities. Early parental loss, limited education, and physical or sexual abuse are also risk factors for PD.

Genetic factors can even be associated with PD. Heightened anxiety, known as behavioral inhibition,

is higher in children of anxiety-disordered parents and in children of adults with PD. As these children have aged, they have been observed to have higher rates of anxiety and phobic disorders.

Precipitating events have been reported in 60–96% of PD cases. Multiple studies also suggest that traumatic early events may figure into the vulnerability leading to PD.

Course and Prognosis

Available evidence suggests that PD is a chronic condition, once criteria for the disorder are met. It is common for patients to report symptoms that they have had for 10–15 years prior to diagnosis. As mentioned previously, the Klein model suggests that spontaneous PAs are the first manifestation of the illness, followed by anticipatory anxiety and then agoraphobia in some individuals.

In fact, most PD patients do not have PAs as their first symptoms. Over 90% have had mild phobic or hypochondriac symptoms prior to the onset of their first PA. The first PA is usually experienced in a phobogenic situation, such as a public place, street, public transportation, crowd, elevator, tunnel, bridge, or open space. Despite this, the Klein model remains largely correct and helpful in conceptualizing the development of the condition and its treatments.

After diagnosis and some sort of treatment, functional recovery occurs in the majority of patients. Poor responses to treatment were associated most consistently with initial high symptom severity and high agoraphobic avoidance at baseline. A poor response is also associated with a low socioeconomic status, less education, longer duration, limited social networks, death of a parent, divorce or unmarried status, and personality disorders.

Treatment

Since the early 1960s, effective psychological and pharmacological treatments for PD have been developed.

Tricyclic Antidepressants (TCAs)

In the 1960s, the TCA imipramine was one of the first effective drug treatments. Important advantages of imipramine include its once-a-day dose, its low cost, and the extensive research that has been conducted on its effectiveness. Its principal difficulties are initial hyperstimulation reactions, significant weight gain with long-term use, and the dangers involved with an overdose. The highly serotonergic clomipramine became the most popular treatment in Europe during the 1970s, 1980s, and 1990s.

Monoamine Oxidase Inhibitors (MAOIs)

During the 1960s, MAOIs were also proven to be effective in the treatment of PD. The most definitive trial was an early comparison of phenelzine and imipramine in the mid-1970s. This was the first trial to suggest that MAOIs might be the most effective medication class, especially if the PD patient is depressed. The biggest drawbacks of MAOIs are the need for a patient to be on a restricted diet and the danger of hypertensive crisis if the diet is not followed. There are also dangers if certain other medications are used, especially certain analgesics and other antidepressants. The principal side effects are insomnia, weight gain, postural hypotension, anticholinergic side effects, and sexual dysfunction.

The reversible MAOIs, brofaramine and meclobemide, have stimulated interest because they require no restrictive diet. However, trials with meclobemide were unable to distinguish medication from placebo, and despite promising early results with brofaramine, its development has been discontinued. There is still active research in this area.

Benzodiazepines (BZs)

High potency BZs (e.g., alprazolam, clonazepam) were developed in the 1980s and are also used in the treatment of PD. In fact, BZs remain the most frequently utilized treatment for PD worldwide, probably because of their quick onset of action, increased efficacy against anticipatory anxiety, low cost, and tolerability. They are frequently utilized in conjunction with the antidepressants. The principal drawback to BZs is the general concern with their abuse potential, although it is alcoholics and opiate or pill addicts that abuse the drug. Abuse in uncomplicated PD patients is extremely rare. Other side effects include the high rate of withdrawal symptoms and relapse that can occur after discontinuing BZ treatment.

Selective Serotonin Reuptake Inhibitors (SSRIs)

More recent studies in the 1990s have demonstrated that the SSRIs are effective, and they are now frequently recommended as the first treatment of choice. This is largely based on the many controlled trials documenting the high tolerability of SSRIs and the decreased rate of jitteriness and hyperstimulation responses often associated with tricyclic antidepressants. They are preferred over benzodiazepines in patients with significant difficulty with depression. Most (70–85%) patients retain their benefit when SSRIs are tapered and discontinued after 12 months of successful treatment.

Psychological Treatments:

Psychodynamic Psychotherapy

Although psychodynamic psychotherapy remains a popular treatment for many psychiatric disorders, including PD, there is limited research demonstrating its efficacy in PD. An emotion-focused treatment for PD has been developed that explores typical fears of being abandoned or trapped as stimuli for panic attacks. This often involves a 12-session acute treatment with 6 sessions of monthly maintenance. Patients are encouraged to identify, reflect upon, and attempt to change problematic feelings and their responses.

Behavioral Treatments

There is a rapidly increasing body of evidence for combinations of exposure-based treatments and cognitive-behavioral therapy (CBT) that are effective in the treatment of PD.

Exposure Treatments

Behavioral treatments, involving *in vivo* exposure, require patients to gradually systematically re-expose themselves to their phobic situations. A large number of studies have documented that 58–83% of patients improve after exposure treatments.

One consistent observation of exposure-based treatments is its long-lasting effects. In one trial with 110 individuals treated with 12 weeks of exposure-based treatment, 74% of the sample achieved panic-free status, and this improvement was maintained in almost all patients throughout a 7-year follow-up. Studies that have compared the use of exposure to CBT have found them to be essentially equal in efficacy. There appears to be little benefit from the combination, although the dropout rate was lower.

Evidence supporting the importance of exposure-based treatments is very clear, but many patients remain symptomatic. In addition, many studies report that between 10 and 25% of patients drop out of the therapy because it is an anxiety-provoking treatment method.

Cognitive-Behavioral Therapy

Cognitive-behavioral therapy is based on the theory that patients with PD interpret physical symptoms in a catastrophic way and that these cognitive distortions need to be challenged and corrected. CBT of PD evolved from early work of Aaron Beck but has been applied to PD primarily by Barlow and colleagues and is called panic control therapy (PCT).

Treatment generally involves an initial education component, which is followed by the identification of critical misinterpretations of panic symptoms. Patients are then taught ways in which they can challenge and correct these misinterpretations. This includes evaluating how likely (or unlikely) the imagined consequences are and how catastrophic it would be even if their worse fears did happen. Most CBT is also combined with interoceptive exposure to the physical symptoms that frighten them. For instance, a patient fearful of dizziness might be spun in a chair.

Although applied relaxation has been shown to be somewhat effective in PD, other studies have demonstrated that CBT, especially combined with interoceptive exposure (i.e., PCT), is more effective than medication.

Most experts would agree that the treatment of PD with pharmacotherapy and a CBT approach – employing a combination of exposure and cognitive therapy – are roughly comparable in efficacy. The most carefully performed trial demonstrating this was a multicenter, 11-week acute trial comparing imipramine to CBT. Both CBT and imipramine performed equally well, but the combination of CBT and imipramine was not proven to be any more effective in the treatment of PD. This trial provided evidence that CBT applied early in treatment did not offer protective effects against imipramine relapse. However, other data suggest that it is protective if given during the discontinuation period.

Selection of Treatments

Pharmacotherapy (BZs or antidepressants) and CBT/exposure treatments appear to be equally effective, although response is perhaps faster with medication treatment and longer term response is better in some patients with CBT/exposure-based treatments. Most often, selection of treatment is determined by patient choice or individual characteristics.

One important issue in the treatment of PD is that the majority of patients do not fully recover with either pharmacotherapy or psychotherapy. For both types of treatment, only 25–45% of patients could be considered fully recovered, despite the excellent progress that has been made since the 1980s. This has led to ongoing research attempts to find more effective treatment methods for PD.

Paranoia

An unreasonable belief held by a person that other people are victimizing him or her; an unreasonable fear of threat.

Paranoid personality disorder

A disorder characterized by a pervasive distrust and suspiciousness of others, such that their motives are interpreted as malevolent.

Definition and Description

Significance and Social Impact of Paranoia

Assessment

Theories of Paranoia

Treatment of Paranoia

Glossary

Causal attribution

An explanation for the occurrence of events.

Delusion

A false personal belief sustained in spite of apparently incontrovertible and obvious proof or evidence to the contrary.

Definition and Description

The meaning of paranoia and paranoid has fluctuated over the centuries. The literal translation of the Greek paranoid is “by the side of the mind” and was used in a general manner to mean crazy or mad. The use of the term paranoid subsided until its resurgence in Germany in the first half of the nineteenth century to refer to a distinct delusional disorder. In the English-speaking world, a distinct confusion of use emerged, with the United Kingdom tending to mirror continental Europe and using the word paranoia to describe systematized delusional insanity. In the United States, the acceptance of Freud’s 1911 psychodynamic model

of paranoia led to the widespread use of the term and to a diminution of any distinctions between delusional and nondelusional paranoia.

The links among paranoia, persecutory delusions, and paranoid schizophrenia remain close but confused. In ordinary language, however, the word paranoid has become general, applied to people who either have unreasonable or unwarranted complaints of victimization unreasonable fears of threat.

At its extreme, such concerns may lead to the label of paranoid personality disorder, defined as a pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent. People with this disorder are described as being suspicious, being cynical, and tending to bear grudges and take criticism extremely badly. Paranoid personality disorder appears to be relatively common in the general population and has been placed on a continuum in which paranoid schizophrenia is seen as a more severe form of paranoia, which is in turn seen as a more severe form of paranoid personality disorder.

Significance and Social Impact of Paranoia

The terms paranoid or paranoia are used repeatedly in political and social contexts. Paranoia and persecutory delusions are also commonly associated with violence. Paranoia has been described as a characteristic of a vast variety of political systems. The societies in Plato's *Republic* and Hobbes's *Leviathan* have been described as characteristically paranoid as have a great number of political systems from Tudor England between the fifteenth and seventeenth centuries, the United Kingdom in the eighteenth to nineteenth centuries, and both the U.S. and Soviet Cold War political systems. Political leaders as individuals (particularly Hitler, Stalin, and Nixon) have also been described as paranoid.

Paranoid delusions have been associated with many violent acts. The M'Naughten rules, the legal basis for an insanity defense, were established after Daniel M'Naughten attempted to kill British Prime Minister Sir Robert Peel in 1843. M'Naughten mistook the prime minister's aide, Edward Drummond, for Sir Robert and shot him instead. M'Naughten was found to be clearly and delusionally paranoid. According to an analysis of the so-called White House cases (individuals who were hospitalized because of their psychotic preoccupation with U.S. politicians), paranoid delusions were common, but the best predictor of arrest for a violent crime after hospital discharge was an arrest for a violent crime before hospitalization. This finding has been generally supported; the likelihood of acting on delusions is generally unrelated to

phenomenology of the delusion but is predicted by the perceived evidential support for the belief, negative emotions, and social functioning.

Assessment

Paranoid ideation can be assessed in its own right as delusional beliefs or as a symptom of schizophrenia.

Delusional classification is complex, and it is often difficult to determine the difference between unusual beliefs and full delusions, between brief episodes and persistent delusions, or between bizarre versus non-bizarre delusions. Thus, continua rather than dichotomous classifications may be appropriate. Delusions are also usually assessed on a variety of parameters: conviction, cultural or stimulus determinants, preoccupation, implausibility, extension (the degree to which the delusional belief involves various areas of the patient's life), bizarreness, disorganization, and emotional commitment.

General psychiatric rating scales include brief assessments of the presence or absence of the symptoms of schizophrenia, including delusional beliefs. A more precise assessment can be obtained using specific research devices. Within such scales, however, delusional ideation is viewed as a part of a whole syndrome rather than as a phenomenon worth examining alone. More specific rating scales and assessment devices have been developed for the assessment of delusions alone.

Despite doubts about the validity and reliability of scales for the assessment of paranoia, the fact that they seem incestuous in their development, and their reliance on doubtful theories of personality structure, diagnosed patients with delusions of persecution score high on these measures, whereas nonpatient samples show predictable associations with other measures of cognitive functioning. However, paranoid ideation is complex. It may be the case that measures applicable for normal and clinical populations are different.

Theories of Paranoia

Theories of paranoia are occasionally subsumed under theories of the development of delusions or schizophrenia. The presumed causes of schizophrenia are not dealt with here; note, however, that nearly all variables believed to influence human behavior have been invoked. Specific theories concerning the etiology of delusions are equally numerous.

Biological Approaches

Medical and psychiatric conditions Paranoid delusions occur in association with at least 105 general

medical conditions. In many nonpsychiatric conditions associated with delusions, delirium (a state of disordered or impaired consciousness combined with an alteration of perceptual functioning or affect) seems important. In such medical conditions, paranoid ideas are presumed to be secondary to the physical pathology. Although it seems difficult to understand the etiology of the abnormal beliefs, it does seem that when the underlying illness is treated the delusions usually disappear. Paranoid delusions are far more common in psychiatric conditions, in which they are often difficult to treat and tend to persist.

Delusions occur in 10–20% of depressed inpatients, with mood-congruent delusions being more common. Delusions occur in up to 70% of manic patients and are usually grandiose, concerning wealth, importance, status, or special powers. As in depression, separating mood-congruent, exaggerated, and abnormal (but nondelusional) beliefs from true delusions in mania is difficult and perhaps of little clinical value.

The presence of delusions is highly likely to lead to a diagnosis of paranoid schizophrenia. Delusions of persecution have been reported in over 60% of patients with a diagnosis of paranoid schizophrenia. Such delusions in paranoid schizophrenia are usually systematized and persistent, as opposed to the fleeting and haphazard beliefs of people with organic diseases.

Genetics Genetic studies of paranoid schizophrenia seem to imply that inherited factors are important but not directly causal. Genetic influences on delusional ideation have received little specific study. When links between genetic factors and delusional beliefs have been made, these usually emerge as post hoc findings from research protocols designed to study paranoid schizophrenia.

Dopamine Dopamine is no longer viewed as a likely contender for the status of single schizophrenogenic factor. However, dopamine-releasing illicit drugs are thought to trigger delusions, especially delusions of persecution.

There is some evidence of dopaminergic abnormalities specific to delusional ideation. However, biological researchers seem to have unwittingly hampered their own investigations in a potentially important area by studying broad constructs such as paranoid schizophrenia. It may be the case, for instance, that disturbance of mental health in general is too broad a concept to be related to specific neurotransmitter mechanisms even if individual psychotic phenomena, such as hallucinations and delusions, may be. Dopamine functioning remains a possible avenue for the investigation of paranoia.

Psychological Approaches

In 1983, Winters and Neale distinguished between motivational and deficit psychological theories of delusional thinking. Deficit theories generally assume that cognitive or attentional abnormalities lead to delusions, whereas motivational theories, in general, assume that individuals develop delusions to explain either unusual perceptual experiences or aversive psychological states.

Psychological deficit theories

Deficits (or excesses) in emotional expression or processing A number of theorists have suggested that delusions stem from excessive or exaggerated emotion. There is some evidence of disruption (or facilitation) of emotional processing in delusions, particularly paranoia. Generally, research examining cognitive processes in persecutory delusions has examined the processing of information related to emotions and the self-concept.

Deficits in logical thinking Because delusions are illogical, many authors have suggested that delusional beliefs occur as a result of deficits in an individual's ability to think logically. In the presence of schizophrenic thought disorder, normal associative links may be disrupted. In the absence of coherent logical associations, affective influences may become dominant and hence delusional ideas may be generated. Although originally advocated by influential authors, there remain reservations about this very general model.

There have been a number of more specific models of delusions involving deficits in logical processes. In delusions, errors or biases in inductive reasoning have been investigated by a number of researchers. These studies have often been cited as evidence of rapid, overconfident, less evidence-based patterns of inductive reasoning in deluded patients.

Perceptual deficits and excesses It has been suggested that paranoid delusions are the products of healthy rational attempts to explain anomalous or disturbed perceptions. There is some evidence in favor of this model, although some investigations have been somewhat unconventional. It has also been suggested that hallucinations may lead to rational delusional beliefs. It might seem quite rational to develop delusional explanations for inexplicable perceptual experiences. There is some clinical evidence of a relationship between deafness and delusions of persecution in elderly patients, for whom the misperception of the conversations of others may serve as fuel for paranoia. Despite this, and the logic of this

approach, there is little experimental support for such a perceptual deficit model in younger patients. One group of perceptual excesses known to lead to delusions is drug-induced hallucinations. However, the delusions seen in drug use seem qualitatively different from functional psychoses.

Theory-of-mind deficits In 1994, Frith suggested that a deficit or abnormality in what is termed the Theory of Mind may explain a number of schizophrenic symptoms. We do not, as a rule, appraise other people's actions and conversation as simple behavioral or verbal patterns. Rather, according to the Theory of Mind, we assume that we can use behavior to divine wishes, hopes, beliefs, intentions, and so forth. Such an understanding is believed to be vital for successful social intercourse. In Frith's model, paranoid delusions are seen as stemming from a lack of understanding of the actions of other people. Although support for this model comes mainly from phenomenological discussions, a number of recent empirical studies have been reported to support it.

Attentional deficits In 1994, Hemsley suggested that delusions stem from a process involving abnormalities in selective attention in which attention is focused on trivialities. This leads to a lack of influence from learned regularities. Clinically, abnormalities in selective attention seem common. However, certain details of the causal, psychological, linking processes seem vague and poorly related to clinical details of delusional beliefs.

Psychological motivational theories

Learning theory The development of learning theory as a major psychological discipline has, of course, led to behavioral theories of delusions. One general approach is to assume that psychotic phenomena are maintained by positive reinforcement. Indeed, behavioral approaches to the treatment of delusions have frequently proved successful, although this tells us little about the origins of delusional beliefs.

Another behavioral approach to delusions is to assume that delusions are reinforcing through avoidance. Patients with schizophrenia may well be sensitive to anxiety and stress, and therefore that avoidance through delusional ideation may be welcome. Overall, however, these models are unsatisfying. The fact that psychopathology gets worse in conditions of stress is not a good test of any model. Such models seem to invoke, but not address, cognitive variables.

Psychoanalytical theories

The paranoid pseudocommunity Some psychoanalytic theorists have suggested that delusions result

from weaknesses in an individual's ego boundaries. If a person's distinction between self and world and between self and fantasy is weak, the distinction between reality and falsehood is assumed to be similarly weak. In this context, it has been suggested that a person frustrated by a lack of social skills seeks refuge in fantasy and daydreams. However, these primitive fantasies, born from frustration, also threaten the ego. Because the defenses (fantasy) are immature, these threats are denied and repressed. Because the individual is not in contact with a normal social network, paranoia develops in a context of imagined and delusional others – the paranoid pseudocommunity.

Although this model appears overly complex, with many assumptions, many researchers have found it persuasive. Empirical data, however, undermine the central thesis that paranoia is born from a lack of social skills. In fact, people diagnosed as having schizophrenia have a higher premorbid social adjustment if they have paranoid symptoms.

Freud More commonly, psychoanalytic theories have invoked defense mechanisms, particularly projection. Freud (in 1911) and many others suggested that delusions represent the externalization of desires, fears, or conflicts. Sigmund Freud's theory of the causes of paranoia has been extremely influential. In essence, it suggests that paranoia develops as a defensive support for a denial of homosexual love. Broad acceptance of this model seems to have shaped American psychiatry's approach to paranoia.

Freud proposed a psychoanalytic theory of persecutory delusions. Paranoid delusions, Freud claimed, are parts of a process protecting the conscious ego from awareness of conflict with unacceptable homosexual impulses stemming from the id. Such homosexual urges are, Freud argued, denied or contradicted and then countered by the defenses of rationalization and projection. A male patient is essentially confronted with the idea that "I (a man) love him (a man)." This is unacceptable, leading to reaction formation and the idea "I do not love him. I hate him." Such inhuman hatred is still unacceptable, and is rationalized as "I hate him because he hates and persecutes me."

Freud's account is colorful, but has been widely challenged. Freud's model suggests that the delusional persecutor is a person for whom the patient expresses secret homosexual love. However, paranoid people frequently do not know their persecutors or even have a specific idea of who they might be. Moreover, many patients fear persecution by members of the opposite sex, who are unlikely to be fueled by repressed homosexual feelings.

It is notable that Freud's model of paranoia includes two elements: a defensive projection or

externalization of threatening material and latent homosexuality. It is possible that the defensive component is more valid than the homosexual part. Psychoanalytic writers after Freud suggested that persecutory delusions serve a defensive function, without necessarily stressing latent homosexuality.

In an more recent variant of this model, Colby suggested that paranoia stems from a tendency of a person to perceive or generate threats to his or her self-esteem combined with a protective mechanism of projection and externalization of the threat to others. In an interesting twist, Colby described a computer simulation model of his theory. A test was conducted comparing the output of his computer model with a real paranoid patient. Because clinical judges were reported to be unable to distinguish the two, the computer model was considered a success. One of the main benefits of Colby's theory is that it is testable. People with delusions of persecution should readily perceive potential threats to self-esteem, and they should also locate the source of such threats as external. Many more recent cognitive investigations of paranoia are compatible with Colby's model.

Camouflaged depression Zigler and Glick suggested that paranoia is a form of camouflaged depression. This suggestion was originally formulated as a statement regarding classification, with paranoia being properly seen as a form of affective disorder. However, the claim is also a causal one. Taking as sources the psychological theories of paranoia previously briefly reviewed, Zigler and Glick claimed that paranoia consists of low self-esteem or feelings of inadequacy (the depression part) covered with defensive projections of these feelings onto others.

Two types of paranoia A subdivision of paranoia has recently been proposed into the rather pejoratively labeled poor-me and bad-me paranoias. In the first form, paranoia is seen as stemming from a low self-esteem, so low that persecution is expected. In the second, paranoia is seen as stemming from defensive processes similar to those suggested by Kinderman and Bentan. Despite weak evidence supporting the subdivision, this categorization has the benefit of being based on theoretical distinctions between different cognitive processes believed to be etiologically important.

Attributional defenses against threats to the self-concept In the attributional model of paranoia, proposed by Kinderman and Bentan, events that might activate an implicit negative self-representations are hypothesized to evoke externalizing (self-protective yet paranoid) causal attributions: "I am not responsible for the bad things that are happening to me, other people are." This reduces the accessibility of self-actual:

self-ideal discrepancies, but it leads to the belief that others have negative views of the self. Such an explanation is consistent with psychodynamic accounts of paranoia and with the suggestion that paranoia represents a form of camouflaged depression. This model may have relevance to "normal" psychology beyond the clinical arena.

Normal emotional processing More recently, psychologists Garety and Freeman have suggested that paranoid thought emerges from normal, rather than excessive or exaggerated, emotional processes. These commentators point out that relatively normal emotional problems (anxiety and depression) are common in paranoia and contend that it is possible that these processes may lead to delusional beliefs.

Although it is an attractive argument, this approach fails to account for why some people with these problems remain simply anxious and depressed, whereas other people become deluded.

Treatment of Paranoia

A range of drug treatments are commonly used in the treatment of psychosis, including paranoia. The most important are antipsychotic drugs (sometimes called neuroleptics), which are now regarded as the preferred medical treatment for psychotic conditions. Antipsychotic drugs may be used in the acute phase of psychosis or prophylactically and have been shown to result in acute symptom management and the prevention of relapse. However, neuroleptics are not perfect treatments. Some patients fail to respond or show only a partial response, and neuroleptic treatment can lead to serious and distressing side effects.

Modern developments in clinical psychology mean that schizophrenia may now be seen as amenable to psychological treatment. In particular, delusional ideas can be addressed successfully using the techniques of reality testing and cognitive restructuring. Relatively straightforward cognitive therapy strategies may be beneficial to deluded patients. A common feature of the cognitive-behavioral therapy (CBT) strategies that have been advocated for use with deluded patients is the avoidance of direct confrontation of the patient.

Kinderman and Bentall described one final therapeutic approach, directly driven by theory. In this approach, the causal attributions made by a severely deluded, paranoid patient are addressed through the use of cognitive therapeutic techniques. External personal attributions for minor negative events (blaming other people for bad events) are thought to be characteristic of paranoia. The use of the techniques of CBT may address this tendency.

It has been suggested, with respect to the teleological and religious quality of many delusions, that a

patient's recovery is heralded by the acceptance of the accidental in life. If the situational-external locus of causal attribution is meaningful, it is essentially an acceptance of the accidental. Such an acceptance may be important in many areas of life. Perhaps paranoid individuals need to learn that, sometimes, strange things just happen. An acceptance of the accidental in life may be psychologically important.

Output Control

CRH Neurons

Stressor-Specific Patterns of Gene Expression

Regulation of Homeostasis and Ingestive Behaviors

Glossary

- Corticotrope** Cell type in the anterior pituitary that synthesizes and secretes adrenocorticotrophic hormone (ACTH), which in turn stimulates glucocorticoid secretion from the adrenal cortex.
- Corticotropin-releasing hormone (CRH)** Peptide hormone that increases the secretion of adrenocorticotrophic hormone (ACTH) from corticotropes in the anterior pituitary.

Magnocellular neurosecretory system

Large neurons in and around the hypothalamus that send their axons directly to the posterior pituitary, where they release the peptide hormones vasopressin and oxytocin into the general circulation.

Median eminence

Functionally, the initial part of the stalk of the pituitary gland along the base of the hypothalamus; its inner layer contains the axons of magnocellular neurosecretory neurons and its outer layer contains the axon terminals of parvocellular neurosecretory neurons.

Paracrine

Chemical messengers that act locally in a general way; in contrast to hormonal messengers that act via the bloodstream and to synaptic messengers that act as specialized intracellular junctions.

Parvocellular neurosecretory system

Small neurons in and around the hypothalamus that send their axons to the outer layer of the median eminence, where they are taken up and delivered to the anterior pituitary by a portal system.

Portal system

A system of veins with a capillary network at either end; used to deliver substances from one capillary bed (as in the median eminence) to another (as in the anterior pituitary).

The paraventricular nucleus of the hypothalamus (PVH) is the most important part of the brain for controlling the stress response because its neurons control the release from the anterior pituitary gland of adrenocorticotrophic hormone (ACTH), which in turn controls glucocorticoid release from the adrenal cortex. In addition to constituting the final common pathway for all centrally mediated stress responses, the PVH (1) controls the release of other hormones from the anterior and posterior parts of the pituitary gland, (2) influences the size of autonomic reflexes mediated by circuits in the brain stem and spinal cord, and (3) modulates eating and drinking behaviors. Furthermore, steroid hormone and neural inputs can dramatically alter the expression of neuropeptide and many other genes in the PVH, with different stressors producing different patterns of altered expression.

Location and Basic Divisions

In all mammals, the PVH lies adjacent to the third ventricle, in the rostral half of the hypothalamus, rostral to the infundibulum or stalk of the pituitary gland. The PVH, together with the supraoptic nucleus, was originally known as the origin of the magnocellular neurosecretory system. That is, under most conditions separate groups of neurosecretory neurons in each of these two nuclei synthesize significant amounts of either vasopressin or oxytocin and release them into the general circulation at the level of the posterior pituitary gland. These peptide hormones (which are nine amino acids long) play especially important roles in controlling diuresis and blood pressure (vasopressin), and in parturition, lactation, and associated social behaviors (oxytocin).

In the 1970s, it became clear that the PVH also has two other divisions. First, it contains neurons that project to the median eminence and that are thus involved in controlling hormone release from the anterior pituitary (the parvocellular neurosecretory system) and, second, it contains neurons that send descending projections to the brain stem and spinal cord – especially to regions involved in autonomic reflexes, the relay of nociceptive information, and somatic motor behavioral responses. Neuroanatomical studies with multiple retrograde tracers demonstrate that there are three essentially separate cell groups in the PVH of the rat: the magnocellular neurosecretory, parvocellular neurosecretory, and descending divisions.

The parvocellular neurosecretory division appears to contain three major cell types. Most importantly regarding stress, it contains virtually all of the neurons that synthesize corticotropin-releasing hormone (CRH) and release it into the pituitary portal system

to increase ACTH secretion from the anterior pituitary. Second, the PVH contains virtually all of the neurons that synthesize thyrotropin-releasing hormone (TRH) and release it into the pituitary portal system to increase thyroid-stimulating hormone secretion from the anterior pituitary. And third, the periventricular zone of the PVH contains a large fraction of the neurons that release somatostatin into the pituitary portal system to inhibit growth hormone secretion from the anterior pituitary.

Neurons in the descending division of the PVH innervate many parts of the brain stem and spinal cord. Best understood, however, are inputs to preganglionic neurons of both the parasympathetic and sympathetic parts of the autonomic nervous system to visceral sensory regions including the nucleus of the solitary tract and parabrachial nucleus, to the periaqueductal gray, and to various parts of the reticular formation. As discussed in the following, these descending projections appear to coordinate autonomic and behavioral responses with neuroendocrine responses elicited from the PVH.

Output Control

As the final common pathway for all types of stress response mediated by the central nervous system, it stands to reason that the PVH receives pathways for all of the relevant stimuli. Thus, it should come as no surprise that the afferent control of the PVH is exceedingly complex. In fact, on the order of 50 different sources of axonal inputs to the PVH have been identified with modern neuroanatomical pathway tracing methods, and in many instances associated neurotransmitters have been identified as well. Each neural input appears to end in relation to more than one cell type in the PVH, and a majority of the neural inputs that have been identified to date end in the region of CRH neurons that control ACTH release.

Neural inputs to parvocellular neuroendocrine CRH neurons fall into a number of functional categories. First, there are inputs that relay sensory information. The best-known inputs of this type arise in three hindbrain regions – the nucleus of the solitary tract, ventrolateral medulla, and parabrachial nucleus – and are known to relay viscerosensitive, and probably nociceptive, information to CRH neurons. Second, there is a direct input from a part of the basal ganglia (of the cerebral hemispheres) known as the bed nuclei of the stria terminalis. The bed nuclei in turn receive inputs from other parts of the cerebral hemispheres – including the ventral hippocampus, amygdala, and prefrontal cortex – that may exert cognitive influences on the PVH. Third, there are direct inputs from certain behavioral state control

nuclei, such as the suprachiasmatic nucleus (which generates the circadian rhythm) and the midbrain raphe nuclei (which may be involved in certain aspects of behavioral state or arousal). And fourth, parvocellular neurosecretory CRH neurons in the PVH receive inputs from many cell groups in the hypothalamus that have complex, as yet poorly understood functions related to homeostasis and behavior.

In addition to neural inputs, the PVH appears to be influenced by humoral inputs, that is, by feedback influences of steroid and other hormones. For example, specific sets of neurons in the PVH express glucocorticoid, mineralocorticoid, estrogen, and thyroid hormone receptors. These hormone receptors may change the plasma membrane electrical properties of certain PVH neurons, but it is becoming increasingly clear that they may also change – either directly or indirectly – the pattern of gene expression in PVH neurons in profound ways.

CRH Neurons

CRH neurons that control ACTH secretion are quite remarkable from a functional point of view. In the first place, they have the traditional role of releasing a factor or hormone (CRH) into the proximal capillary plexus of the hypothalamo-hypophysial portal system – at the level of the external layer of the median eminence. The axon of these neurons initially extends laterally from the cell body in the PVH and then arches ventrally through the region of the fornix before curving medially around the ventrolateral border of the hypothalamic ventromedial nucleus to enter the median eminence, where it ends in a rich proliferation of terminal boutons. Peptides (such as CRH) released from these terminals are of course transported via the portal system to act as hormones in the anterior pituitary (for example, on corticotropes).

In addition, however, there is evidence that released substances may also act in a paracrine way within the median eminence itself. For example, it would appear that CRH can act presynaptically to inhibit the release of gonadotropin-releasing hormone (GnRH) at the level of the median eminence. This may account in part for the inhibition of gonadal steroid hormone release observed after some types of stress.

Furthermore, the results of lucifer yellow dye cell-filling experiments indicate that the axon of parvocellular neurosecretory neurons generates terminal boutons of passage in the hypothalamus, on its way to the median eminence. This raises the distinct possibility that these neurons also form classical chemical synapses within the hypothalamus itself. Thus, the evidence suggests that the axon of CRH parvocellular

neurosecretory neurons in the PVH can have spatially segregated hormonal, paracrine, and synaptic effects.

In addition to the fact that ACTH-controlling CRH neurons receive more than 50 sources of neural inputs, and that their axon can exert hormonal, paracrine, and synaptic effects, it is now clear that they can also express a bewildering complement of neurotransmitter and/or neuromodulator genes – on the order of 10 to 20. In addition to CRH, they include vasopressin and angiotensin, all of which act synergistically to secrete ACTH, as well as enkephalin, neurotensin, and cholecystokinin, which do not appear to act on corticotropes but may instead interact with receptors at the level of the median eminence and/or hypothalamus.

Stressor-Specific Patterns of Gene Expression

Shortly after CRH was characterized and antibodies to it were raised by Vale and his colleagues, it became clear from multiple labeling immunohistochemical studies that the ratio of putative neurotransmitters in individual PVH neurons can vary dramatically, depending on the endocrine status and stress history of the animal. This was first observed in adrenalectomized rats, in which high levels of previously undetected vasopressin were found in CRH neurons, indicating that vasopressin mRNA levels are much more sensitive to the negative feedback effects of glucocorticoids than CRH mRNA levels.

Since then, a vast amount of experimental evidence has suggested that many forms of stress alter patterns of neuropeptide gene expression in the PVH, as well as in numerous other parts of the brain, and that each form of stress may be accompanied by a specific and distinct pattern of altered gene expression in the brain. For any particular gene, the occurrence, magnitude, and time course of altered expression depend on the type, magnitude, and time course of a particular stressor or pattern of stressors. Thus, it is clear that stressors do not produce synchronous changes in brain gene expression.

Interestingly, a number of neurotransmitter or neurotransmitter-related genes are expressed across cell types in the PVH. For example, under appropriate conditions, CRH, vasopressin, angiotensin, dynorphin, and tyrosine hydroxylase (the enzyme that synthesizes dopamine) are expressed in parvocellular neurosecretory, magnocellular neurosecretory, and descending neurons of the PVH, and a particular stressor or condition may influence gene expression differentially in different cell types. In the rat, corticosterone (the principal endogenous glucocorticoid) decreases CRH and vasopressin mRNAs in parvocellular neurosecretory

neurons, increases CRH mRNA but has no effect on vasopressin mRNA in magnocellular neurosecretory neurons, and increases CRH mRNA but has no effect on vasopressin mRNA in descending neurons.

Regulation of Homeostasis and Ingestive Behaviors

A wide range of experimental work has shown that the PVH is part of the circuit or system that controls eating and drinking behaviors, that is, ingestive behaviors, and that descending projections from the PVH (probably to the periaqueductal gray or nearby areas) are involved in these responses. This involvement in behaviors that play a critical role in maintaining homeostasis for metabolic fuels and for body water is perhaps not surprising in view of the neuroendocrine and autonomic projections of the nucleus. Regarding metabolic control, recall that virtually all parvocellular neurosecretory CRH and TRH neurons (controlling adrenal glucocorticoid and thyroid hormone secretion, respectively) are found in the PVH, as are a majority of the somatostatin neurons that inhibit growth hormone release. And regarding body water regulation, recall that the PVH contains a major population of magnocellular neurosecretory vasopressin (antidiuretic hormone) neurons. In addition, the PVH establishes major bidirectional connections with brain stem and spinal cord circuits that mediate both sympathetic and parasympathetic reflexes, some of which are undoubtedly involved in metabolic and body water regulation.

In summary, the PVH consists of three functionally distinct divisions with essentially motor functions: parvocellular neurosecretory, magnocellular neurosecretory, and descending, with inputs to autonomic and somatomotor control systems. As such, the PVH is in an ideal position to integrate neuroendocrine, autonomic, and behavioral responses to particular stressors, which is a hallmark of hypothalamic function in general. Because the PVH contains few if any interneurons, and recurrent axon collaterals have

been difficult to identify unequivocally, this functional integration appears to be mediated by neural inputs, virtually all of which innervate more than one functional division, and perhaps by humoral inputs as well. In addition to containing the CRH neuroendocrine motoneurons that control ACTH release, the PVH is critical for the integrated behavioral, autonomic, and neuroendocrine responses that assure a relatively constant supply of nutrients and body water.

Why Parenting Can Be Stressful

Types of Parenting Stress

Effects of Stress on Parents

Effects of Parenting Stress on Children

Interventions for Parents and Children

Glossary

<i>Child temperament</i>	An enduring pattern of biological and physiological responses to the environment.
<i>Coping</i>	Psychological processes that allow an individual to regulate negative emotions and behavior to adapt to stressful situations.
<i>Daily hassles</i>	Normal or typical life experiences that increase negative affect and interpersonal distress by virtue of their high demands and low satisfaction.
<i>Major life events</i>	Exceptional but time-limited life circumstances that produce stress in an individual by acutely increasing negative affect, interfering with daily functioning, and creating change in relationships and routines.
<i>Parenting stress</i>	Pattern of adverse psychological and physiological reactions resulting from the demands of being a parent.
<i>Self-efficacy</i>	An individual's perception of his or her competence in completing the tasks that define a particular domain.
<i>Social support</i>	Interpersonal relationships that meet the emotional and instrumental needs of individuals experiencing distress.

Raising children is often a rewarding and positive experience, but it is also a challenging task that is inevitably stressful at times. Parenting requires a high level of effort and emotional involvement that can be overwhelming. It also involves a wide range of skills that must be used in a flexible manner. Parenting involves meeting the basic needs of children, socializing them to culturally appropriate rules of behavior, and promoting their self-esteem and emotional well-being. In the past 25 years, increasing attention has

been paid to the stress of raising children and the effects of parenting stress on caregivers and families. Parenting stress has been defined as a pattern of adverse psychological and physiological reactions resulting from attempts to adapt to the demands of being a parent.

Why Parenting Can Be Stressful

Parenting Tasks

On a daily basis, parents must meet children's survival needs by providing them with shelter, food, clothing, and other necessities. They must ensure their physical safety by carefully monitoring their activities in different environments and by ensuring that proper medical attention is received. Parents must also meet their children's emotional needs by providing attention and affection in order to promote a healthy self concept and socioemotional development. Parents are also responsible for socializing children. They teach them how to adapt to their sociocultural environment by monitoring their behavior and reinforcing culturally appropriate responses. Parents also act as the primary models for regulating negative emotions and coping with distress in culturally specific ways. Parents actively help younger children cope with anger and disappointment by emotional scaffolding and redirecting attention. With older children, parents assist in problem solving and anticipating consequences prior to responding to a situation. Parents provide negative consequences to dissuade inappropriate anger responses such as aggression and prolonged displays of negative affect; in contrast, they praise and reward behaviors that are appropriate or polite. Finally, parents are responsible for introducing children to the larger community outside the family by providing opportunities for peer interaction, formal learning in school, and group activities. In all, parents are expected to carry out a wide variety of tasks that enable their children to successfully adapt to the demands of their sociocultural group and ultimately to become contributing members of their group.

Parenting Must Change as Children Develop

As children grow and develop, their needs and reliance on parents continually change. Being a parent is thus not a singular transition into a static role but rather a set of transitions within a dynamic role that is continually evolving to meet the changing needs of children. Furthermore, the role of being a parent

requires synchrony between parents and children, and this synchrony falls largely on parents to achieve, especially when children are younger. Thus, children's developmental stages influence the amount of stress experienced by parents. For example, caring for a newborn is a time of high stress, particularly for the first-born child. In addition to the change in responsibilities and life style that occurs with the first child, newborns demand round-the-clock intensive care-taking. The preschool age has also been identified as stressful because parents must provide constant care and supervision while negotiating limits with their children as they begin to establish their independence. Other developmental stages provide their own set of challenges: entry into school, with exposure to and judgment by the larger community; adolescence, with increased demands for independence and a renegotiation of the parental role; and finally launching, facilitating the children's assumption of adult roles. Each developmental stage demands different characteristics of the parent; thus, parents differ on which stages they find easier or more difficult.

Parenting Must be Adapted to Children's Temperament and Special Needs

In addition to development, parents must adapt their interactions and interventions according to their child's individual temperament. There is not a single style of parenting that is ideal for every child. Instead, for example, parents must adapt their style to be more soothing for children with difficult temperaments who have problems regulating negative affect and more firm for children with temperaments that are high in novelty seeking. Children with more extreme temperaments or temperaments that differ from their parents can be experienced as more stressful. In addition, disabilities, developmental delays, chronic illnesses, or other special needs of children influence the level of stress experienced by parents. Such children typically require more physical care and more supervision; they also require that parents adjust to the loss of their perfect child and learn to cope with the medical and educational systems. Similarly, children with behavioral or emotional problems cause more stress for their parents.

Balancing Parenting with Other Roles

Parenting stress can also result from difficulty in balancing parenting responsibilities with other adult roles, particularly the roles of spouse and worker. For example, the transition to parenthood has been associated repeatedly with decreased marital satisfaction. The overwhelming, new responsibilities that come from the arrival of a newborn, combined with

fatigue and the intense demands of caring for an infant, decrease the time and attention available for the marital relationship, which in turn may decrease marital satisfaction. Over time, parents must learn to balance the needs of all in the family, including the needs of their spouse and their own needs. Parents' difficulty in finding time and energy to meet their own needs is a major contributor to parenting stress.

Balancing work with parenting is another source of stress. Parents must make provisions for routine child care and also accommodate nonroutine events such as children's illnesses and school snow days. The rising demographic trend in first-world nations for dual-wage-earner families indicates that a high number of new mothers will continue to work outside of the home after a child is born. Thus, many families will be faced with the difficulties of balancing multiple roles.

Circumstances of Child Rearing

Specific circumstances of childrearing can exacerbate the level of stress experienced by parents. These circumstances include poverty, number of children, amount of social support, marital status, and physical or mental illness in parents. These stressors impede parents' efforts to care for their children. Thus, for example, single parents raising a number of children in poverty are likely to experience more stress than parents raising children in more favorable circumstances.

Types of Parenting Stress

Major Life Events

Early research on parenting stress focused on the consequences of major life events that increased emotional distress in parents and complicated normal parenting tasks. These major life events, such as death of a spouse, loss of employment, or divorce, were viewed as atypical of the everyday experience of parenting and were thought to increase parental distress and dysfunction and to impair effectiveness of meeting children's needs. Likewise, parenting stress was examined in relation to parenting children with a developmental disability, chronic physical illness, or an emotional disorder. This research did indeed indicate a link between major life events and various indices of parent, child, and family functioning. Parents who were coping with out-of-the-ordinary difficult circumstances reported reduced emotional well-being and increased psychopathology. They were also observed to have less optimal parenting skills. In turn, their children showed more psychopathology and lower social competence. However, a

shortcoming of the major life events model is that it focuses on low-frequency events that cluster in high-risk populations with many problems. The life events model fails to capture the minor stress incurred by all parents in meeting the daily demands of childrearing.

Chronic Minor Stressors

Current research on stress in adults focuses on both major life events and the more mundane chronic stress stemming from meeting the demands of daily living. For parents, minor stressors are the daily hassles of meeting children's needs, including monitoring children's behavior, physically caring for children (i.e., feeding and cleaning), and balancing conflicting schedules of work and family life. Thus, the construct of minor stressors, or parenting hassles, refers to commonly occurring events in all families. Crnic and others argue that the chronic nature of these daily hassles of parenting may make them more likely to adversely affect family functioning than are major life events that occur infrequently. Furthermore, they argue that minor stress, or daily hassles, can provide a more universal model of the effects of stress on family functioning.

Perceived Stress

Stress resulting from daily hassles is largely a subjective experience. Some parents can cope with challenging aspects of parenting better than others. Accordingly, all parents do not experience the daily hassles of parenting in the same way. For example, coping with children's misbehavior is so stressful for some parents that changes occur in the parents' mood and level of anxiety; whereas for other parents these are merely transient annoyances of the day. Individual differences in perceptions of parenting stress reflect both biological and environmental influences. Adults bring to parenting different personality styles, different emotional resources, different coping skills, and different childhood experiences of being parented. Indeed, the best estimate of emotional well-being and functioning in parents is the level of well-being and functioning prior to becoming a parent, that is, prior to the birth of the first child. Personality styles most susceptible to experiencing stress are those marked by the prevalence of negative affect (i.e., moodiness and irritability) and trait anxiety (i.e., intolerance of uncertainty and intolerance of arousal). In addition, parents who as children experienced less positive relationships with their own parents and insecure attachments are more likely to perceive their experiences with their own children as less positive.

Critics of the minor stressors, or daily hassles, approach argue that the construct of daily hassles is inherently subjective, whereas major life events can be assessed more objectively. These critics argue that perceptions of minor hassles are confounded with the outcome measures of family functioning; for example, there is an overlap between perceiving parenting as burdensome and perceiving children's behavior as problematic. On the other hand, individual differences clearly exist in parents' ability to cope with the everyday challenges of parenting. And a large literature verifies that perceptions of events influence functioning.

Effects of Stress on Parents

Parental stress from both major life events and from daily hassles has been shown to negatively impact parents' emotional well-being, marital satisfaction, and parenting behavior.

Parental Mood and Emotional Well-Being

Parenting stress is associated with lower emotional well-being in parents. That is, parents who report more daily hassles in parenting and/or more major life events describe themselves as having less life satisfaction and more negative mood and emotional distress. There is some evidence that stress from daily hassles relates more strongly than does stress from major life events, but stress from each of these sources contributes to lower emotional well-being. In addition to the negative impact on their own emotional well-being, parents with high stress also report a less positive outlook on parenting and less satisfaction in the parental role. Furthermore, they tend to experience less pleasure in and enjoyment of their children. Not surprisingly, they report lower feelings of self-efficacy in the parenting role; that is, they feel less competent in carrying out their parental responsibilities and less confident that their efforts will have a positive impact on their children. For some parents, high levels of parenting stress contribute to psychological disorders, such as depression and anxiety. For example, mothers with higher parenting stress from low-birth-weight or medically ill infants are at higher risk for developing postpartum depression.

A bidirectional relationship exists between parenting stress and negative parental mood. Parenting stress can increase negative parental mood, but, conversely, negative mood may also increase perceptions of parenting stress. Parents with negative mood are more likely to attend to their children's negative behaviors, attribute negative intent to ambiguous behaviors, and have a decreased threshold for aversive behaviors.

Marital Satisfaction and Social Support

The stress of parenting can also affect the marital relationship. When parents feel competent in their abilities to care for their children and cope effectively with daily hassles of parenting, the marital relationship can be strengthened and serve as a solid foundation of the family. However, when high levels of parenting stress are experienced, parents often report lower levels of marital satisfaction. One reason for the decrease in marital satisfaction may be that parents who experience high levels of parenting stress have less time and emotional resources to devote to the marital relationship and to meeting their spouse's needs. Another reason may be that high levels of parenting stress increases the frequency of marital conflict and demonstrations of negative affect toward the spouse. Because the primary social support in parenting is typically the spouse, the decrease in marital satisfaction typically decreases the support a parent experiences in the role of parenting. However, others (such as grandparents) may increase the support that they provide so that a parent does not perceive a decrease in the overall support that he or she receive in the parental role.

Again bidirectional relationships occur. Parenting stress can impair marital satisfaction, but conversely, marital satisfaction can mitigate parenting stress. If parents work together, divide responsibilities, and support one another's efforts, the daily hassles of parenting are less stressful.

Parental Interactions with Children

Parenting stress can also have an adverse effect on parents' behavior toward their children. Parents who experience high levels of stress report more negative and coercive interactions with their children; similarly, they report using more authoritarian and power-assertive discipline strategies. They also describe themselves as less involved with their children. These disparate self-reports are suggestive of inconsistent management techniques. Indeed, high levels of stress have been associated with parents' reports of inconsistent disciplinary styles, that is, alternating between setting harsh and rigid limits for their children to being overly lax and permissive. Although much research has established that stressed parents report negatively on their parenting skills, it is less clear that their actual parenting skills are impaired. Research on observed parenting behaviors has been equivocal, although there is some evidence that mothers are more irritable with their children on days when they have experienced more minor stressors. Thus, parents who report higher levels of stress in caring for children may be less likely to initiate

pleasurable interactions with the children and may be less able to use proactive disciplinary strategies.

Effects of Parenting Stress on Children

Parenting stress has repeatedly been found to relate to children's social competence and to behavior problems. Indeed, it is thought to be a primary contributor to the development of psychopathology in children. Again, however, much of this research is based on parental reports. Parents who report high stress describe their children as less socially competent and as having more behavior problems, both externalizing and internalizing problems. These parents also describe their children as exhibiting behaviors consistent with insecure attachments. Limited research using teacher reports and children's self-reports provides some support that parents' negative views may be accurate. Teachers rated the children of highly stressed parents as less socially competent, and children reported more adjustment problems when their parents were highly stressed.

How Might Parenting Stress Affect Children's Outcome?

Parenting stress negatively affects parents' interactions with their children, and the negative interactions, in turn, negatively impact child adjustment. In other words, parenting stress may lead to critical and negative parent-child interactions as well as inconsistent discipline; then these changes in parenting may have negative effects on the children's attachment, self-esteem, and behavior. Another way that parenting stress may affect children's outcome is through modeling affect and behavior regulation. Children observe how parents cope with frustrating situations and how they regulate negative emotions and impulsive behaviors. Parents who experience high parenting stress may model poor regulation of negative affect and more reactive behavioral responses to frustration. Finally, children may be directly experiencing some of the same factors that are causing stress in their parents, such as overcrowding.

Bidirectional effects occur in this arena as well. Parents are crucial in shaping children's behavior, but children also shape adults' parenting behavior. The bidirectional nature of parent-child interactions can create coercive relationships. In these relationships, parents' irritability and less-sensitive parenting fuel behavior problems in children, which evoke further punitive and negative parental behaviors. The cyclical interaction of parents' reactions to stressful circumstances and children's aversive behavior can reinforce a maladaptive pattern of interactions that can lead to

chronic stress in the family environment and can place children at higher risk for delinquency.

Interventions for Parents and Children

With increased attention to the potentially harmful effects of stress on parents, the study of how to promote resiliency in parents has gained increasing attention. Social support and active coping skills have emerged as two primary areas of intervention for relieving parental stress. Social support has been related to decreases in self-reported parental stress. Being connected to others, sharing difficult experiences, and receiving help with the day-to-day care of children reduces parenting stress. Teaching parents strategies for coping with the daily hassles of parenting has also been shown to reduce stress in the parental role. Successful coping involves adapting to the daily hassles of parenting by anticipating problems and having a plan for actively addressing them. For some parents, coping may involve monitoring their children's behavior and environment in order to circumvent the escalation of problem behaviors; for others, it may involve establishing predictable daily routines for children and scheduling periods for taking time off, when another caregiver (e.g., spouse, grandparent, or babysitter) can provide respite care. Specific programs that teach effective parenting skills seem to reduce stress by increasing parents' confidence and efficacy in managing children's problem behaviors. Likewise, interventions that teach young children social problem-solving skills can also decrease parents' stress and increase positive parent-child exchanges. Finally, interventions to decrease parenting stress at the larger community level are also needed to support families with children. Systematic efforts to provide high-quality, affordable child care for working parents, job flexibility for balancing

the demands of full-time employment and parenting, and community recreation programs for families will help reduce the burden of parenting and enhance parents' ability to care for their children.

Summary

Glossary

Dopamine

A catecholamine neurotransmitter that plays a pivotal role in several key functions of the brain. Normal dopamine neurotransmission in brain is vital for normal motor function. The abnormal movements and deficiency in motor control that characterize Parkinson's Disease are due to a deficiency in central dopamine consequent on the degeneration of dopaminergic neurons.

L-DOPA (Levodopa)

3,4-dihydroxy-L-Phenylalanine is the immediate precursor of dopamine in its biochemical synthesis. Since L-DOPA can cross the blood brain barrier, it is used clinically in the management of Parkinson's Disease to drive increased dopamine synthesis.

Parkin

An E3 ligase protein that normally tags alpha synuclein protein molecules with ubiquitin. This Parkin-induced tagging (ubiquitination) of alpha-synuclein, triggers alpha-synuclein degradation by the cell proteasome. In many cases of inherited Parkinson's disease, however, Parkin is abnormal and fails to ubiquitinate alpha synuclein. As a consequence, synuclein does not undergo degradation. Rather, it accumulates in Lewy bodies, which leads to dopaminergic cell dysfunction and death.

Parkinson's disease (PD)

The second most prevalent neurodegenerative disorder of the Western world that leads to abnormal movements and loss of motor control and function. Specifically, the clinical features include slowness of movement (bradykinesia), muscular rigidity, resting tremor and postural instability. PD is characterized

Substantia nigra

by the appearance of intracytoplasmic inclusions called Lewy bodies in dopamine neurons in the substantia nigra and the progressive loss of these neurons. Lewy bodies are enriched in filamentous α -synuclein and other proteins that are often highly ubiquitinated. The majority of PD cases are sporadic and of unknown origin, but several genes have been identified that, when mutated, give rise to rare, familial forms of the disease.

A midbrain nucleus of the basal ganglia complex that controls motor function. The pars compacta of the substantia nigra contains the cell bodies of the dopaminergic neurons that project to the striatum in the forebrain. Degeneration of these neurons is the most prominent neuropathological feature of Parkinson's Disease and is thought to be the prime cause of the disorder.

Synucleins

Small, soluble proteins expressed primarily in neural tissue and in certain tumors. The family includes three known proteins: alpha-synuclein, beta-synuclein, and gamma-synuclein. Mutations in alpha-synuclein are associated with rare familial cases of early-onset Parkinson's disease, and the protein accumulates abnormally in Parkinson's Disease, Alzheimer's Disease, and several other neurodegenerative illnesses. Alpha synuclein has also been implicated in non-familial (sporadic) PD, but the mechanism has yet to be determined.

Ubiquitin proteasome system

Molecular system by which misfolded proteins are tagged with polyubiquitin for subsequent degradation by the proteasome of the cell.

Clinical Features of Parkinson's Disease

Parkinson's disease (PD) is a slowly progressive, degenerative, central nervous system disorder. First described by James Parkinson in 1817, it is a movement disorder that results from the death of dopamine neurons in the substantia nigra. The substantia nigra is located in the midbrain region of the brain. It consists of two parts: the pars compacta (SNc) and the pars reticulata (SNr). The SNc produces dopamine and is the part that degenerates in PD. After 50% of the dopamine neurons and 75–80% of striatal dopamine is lost, patients start to show symptoms

of PD. Associated with the loss of dopamine is the presence of protein-containing deposits known as Lewy bodies. It is not known what actually initiates the development of PD.

Approximately 1 million patients worldwide have PD, with approximately 60 000 new patients diagnosed per year. The average age of onset is 60 years old; 5–10% show symptoms prior to age 40; 3% show symptoms after age 65, and 10% show symptoms after age 80.

To be diagnosed with PD, the patient must have at least three of four cardinal signs: rest tremor, bradykinesia (slowness of movement), rigidity, and loss of balance. Pharmacologically, PD is differentiated from clinically similar disorders by the absence of secondary causes and by the presence of a good response to the medication L-dopa. Definitive diagnosis of PD can only be made by autopsy.

Parkinsonism

Parkinsonism is a clinical syndrome that may share some features with PD, secondary to a variety of etiologies. These etiologies include infectious, vascular, pharmacological, toxic, metabolic, structural, and various degenerative disorders.

Clues Suggesting Atypical Parkinsonism

- Early onset of, or rapidly progressing, dementia
- Rapidly progressive course
- Supranuclear gaze palsy
- Upper motor neuron signs
- Cerebellar signs: dysmetria or ataxia
- Loss of bladder/bowel control
- Early symptomatic low blood pressure
- Early loss of balance

Clues to the Etiology of Parkinson's Disease

For decades scientists knew that the substantia nigra in the midbrain of Parkinson's patients show loss of dopamine nerve cells, but what caused this loss remained elusive. Von Economo's encephalitis, which started as an epidemic in Europe in 1918 and then spread worldwide was associated with symptoms similar to PD in 80% of survivors. This condition was termed postencephalitic parkinsonism.

An important breakthrough in the pathophysiology of PD occurred in the late 1950s when researchers gave rats powerful antipsychotic drugs that blocked dopamine nerve cells. In the 1960s, scientists used the toxin 6-hydroxy-dopamine in animals to destroy these cells and produce a rat model of PD.

Finding effective treatments for PD proved more difficult because dopamine does not pass directly into the brain. As depicted in the movie *Awakenings*, doctors in the late 1960s began to give patients the dopamine precursor L-dopa, which crosses the blood–brain barrier and is converted into dopamine.

In the 1980s, a sudden outbreak of severe PD appeared in young Californian drug addicts. These addicts had used a drug contaminated with 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP). This chemical is converted to MPP⁺ in the brain, damaging and killing dopamine cells in the substantia nigra. This inadvertent discovery created a second animal model with which to explore the disease.

Oxidative Stress

Damage from oxygen may be one cause of PD. Oxygen free radicals are oxygen molecules that carry an extra electron. They are destructive because in excessive amounts they chemically attack the components of the cell, including proteins, mitochondria, DNA, and lipids in cell membranes. One of the major problems of normal aging is an increased level of these free-radical-damaged proteins, along with damaged DNA and lipids.

Recent research by Bennett at the University of Virginia isolated complex I from the mitochondria of the brains of PD patients. They discovered that the complex I assembly in Parkinson's had 50% more damage from oxygen. The complex I in the brains of PD patients also had evidence of not being properly assembled and had reduced electron flow.

Environmental Stresses and Parkinson's Disease

Toxins and Parkinson's disease

Rural living and pesticide exposure Although studies in the past pointed to an association between rural living and PD, the results of the most recent studies are quite inconsistent. Because there are many specific exposures associated with living in rural areas, recent studies have attempted to measure these exposures in order to explain the association between PD and areas of low population density.

Three recent studies have found an association between PD and agricultural work. A German study reported an elevated and significant relative risk associated with mushroom harvesting during childhood and adolescence, but no association was found with previous farm activity or employment in agricultural work, living on or near a farm, having contact with farm animals, or being involved in slaughtering

animals. Well water has also been implicated in PD; recent studies in Italy and Spain found a positive association between drinking well water and the risk of PD.

The similarity between the structures of the MPP⁺ and the herbicide paraquat encouraged the investigation of a possible relation between pesticide exposure and PD. A study in Taiwan indicated that the incidence of PD was two times greater in people who had used both paraquat and herbicides/pesticides than in those exposed to pesticides and herbicides alone.

Previous studies found a substantially increased rate of PD among city dwellers who gardened as a hobby. Recent studies have consistently shown an increased risk of PD with pesticide exposure, and in some, this achieved statistical significance. A 2000 California-based study showed that individuals with high-level herbicide exposure had a 70% increased risk of developing PD, compared with those who were not exposed. People who used insecticides in the garden showed a 50% increased risk of developing PD compared to those who had never been exposed to home pesticides of any type. In-home use of insect-killing chemicals was associated with a 70% increased risk of developing PD compared with no use of pesticide.

Metal/industrial exposure Several early case reports described Parkinsonian symptoms in association with manganese mining fumes and accidental industrial poisoning. A recent study of 15 welders with Parkinsonian symptoms showed that the welders had an earlier onset of symptoms. Another study reported that counties in Michigan with iron and copper industries had higher PD mortality rates.

Higher mortality rates from PD are reported in regions with paper and chemical industries. More PD patients than controls reported that they had wood paneling in their homes; this may implicate wood preservatives in the etiology of PD.

Head Injury

Head injury has been implicated in the etiology of PD, possibly through mechanisms that are involved in the inflammatory process. Several recent studies found significant risks associated with head trauma, and several well-known boxers are known to have PD.

Smoking

Many epidemiological studies have shown smoking to be protective for PD. A recent prospective study involving the Honolulu Heart Study supported the idea that nicotine may be protective for PD. Other case-control studies, however, do not support the

claim that smoking is protective for PD; the previous negative association was explained by the fact that smokers die sooner than nonsmokers.

Diet and Antioxidants

A low-calorie diet may help to reduce the risk of PD. A team from the U.S. National Institute on Aging found a long-term reduction in caloric intake protects rhesus monkeys from developing the disease; they also had higher levels of a growth factor, glial cell line-derived neurotrophic factor (GDNF), which may protect brain cells from destruction.

The role of dietary antioxidants has been examined in the etiology of PD. According to the oxidative stress model, an increase in antioxidants prevents damage and death to the dopaminergic cells by scavenging more free radicals. Epidemiological studies examining the association between antioxidant consumption, including vitamin E, C, and A, have not shown a consistent role.

Vitamin B₆ is essential for the metabolism of protein and for brain function. In a study of more than 5000 people, Dutch researchers found those who reported taking in the most vitamin B₆ were approximately half as likely to develop PD as those who consumed the least of this vitamin.

High levels of the amino acid homocysteine can damage brain cells. To see whether a higher intake of folate and vitamins B₆ and B₁₂, which can reduce homocysteine levels, also reduced the risk of PD, researchers followed 5289 men and women ages 55 and older. The researchers found no association between the consumption of B₁₂ or folic acid and the risk of developing the disease; however, the more B₆ people consumed, the lower their risk of PD.

Interactions between Genes and Environment

Genes, Cell Death, and α -Synuclein

No one single underlying factor has been shown to cause PD. Most current research shows that it is a complex multifactorial disease resulting from interaction between one or more genes and the environment. The genes that cause inherited PD can involve the proteins α -synuclein, parkin, and ubiquitin. α -Synuclein forms a major component of Lewy bodies, a classic pathological finding in PD patients.

The discovery of the dominantly inherited gene (α -synuclein, SCNA gene, PARK1) was first described in the Contursi region of Italy. This discovery developed the recognition of a direct role for genetics in PD. Abnormally high levels of α -synuclein, which is produced in dopaminergic cells, may play an

Table 1 Medications^a

<i>Medication</i>	<i>Mechanism</i>	<i>Examples</i>
L-dopa	Crosses the blood–brain barrier and is converted into dopamine	
MAOIs	Block dopamine metabolism	Selegiline, rasagaline
Dopamine agonists	Act directly on dopamine receptors (D1 and D2) to take the place of dopamine	Bromocriptine (Parlodel), pergolide (Permax), pramipexole (Mirapex), ropinirole (Requip), apomorphine
NMDA antagonists	Block excitatory receptors	Amantadine and flumadine
COMT inhibitors	Block the breakdown of L-dopa in the bloodstream, allowing more L-dopa to cross the blood–brain barrier	Tolcapone (Tasmar), entacapone (Comtan)
Anticholinergics	Decrease the activity of acetylcholine (a balancing neurotransmitter)	Trihexyphenidyl (Artane), benztropine mesylate (Cogentin)

^aCOMT, catechol-O-methyltransferase; MAOIs, Monoamine oxidase inhibitors; NMDA, N-methyl-D-aspartic acid.

important role in the death of these cells. In patients with the defective gene, synuclein accumulates, causing dopamine neurons to become more vulnerable to neurotoxic insults. Normally, two other molecules, parkin and ubiquitin, are involved in the natural self-destruction of synuclein in the natural process of programmed cell death called apoptosis.

Genes, Cell Death, and Ubiquitin

Recessively inherited juvenile parkinsonism (AR-JP, PARKIN, PARK2) is one of the most common forms of familial PD. AR-JP is characterized by the selective and massive loss of dopamine neurons in the substantia nigra of the midbrain and the absence of Lewy bodies (the pathological hallmark of PD). Parkin mutations in this form of PD cause the failure of proteolysis mediated by the ubiquitin system and the accumulation of protein, causing dopamine nerve cell death.

Emotional Stress and Parkinson's Disease

Emotional stress increases the symptoms of PD, including the worsening of tremor. Depression in Parkinson patients is common, with some estimates reaching 50% of those affected. Biochemical changes in the brain involving serotonin, catecholamines, and dopamine and emotional responses to chronic disease play a role.

Encouraging patients to perform as many daily activities as possible and to follow a program of regular exercise can help people with PD maintain mobility. Recent research suggests additional benefits of exercise, including neuroprotective effects. Physical and occupational therapy can help patients maintain or regain muscle tone, maintain range of motion, and learn adaptive strategies. Music therapy has been shown to improve slowness in PD.

Caring for a spouse with PD is associated with emotional and social stress, underlining the importance of also assessing the needs of caregivers. One

study showed that spouses of PD patients had more severe depression and that a higher proportion reported tiredness, sadness, and less satisfaction with life than healthy elderly subjects. Caregivers can benefit from learning about the physical and psychological effects of PD and about ways to enable patients to function as well as possible. Because such care is tiring and stressful, caregivers may benefit from support groups.

Medications Used for Parkinson's Disease

The medications used for PD patients compensate for the loss of the dopamine-producing cells by either increasing dopamine levels or simulating the effect of dopamine in the brain (Table 1). Dopamine cannot be given directly because it does not cross the blood–brain barrier.

Summary

Many stressors have been associated with the development of PD. Complex interactions among the environment, oxidants, toxins, genes, and emotions play a role in the etiology of PD.

Types of Peacekeeping Missions
Unique Stressors of Peacekeeping
Psychological Impact of Peacekeeping
Conclusions and Recommendations

Glossary

<i>Peace enforcement</i>	A process by which military personnel necessitate a cessation of hostilities and facilitate a peace process.
<i>Peacekeeping</i>	Maintaining a military presence that increases the likelihood of peace and reduces the likelihood of fighting among two or more formerly warring parties.
<i>Peacekeeping roles</i>	Duties such as guarding and patrolling vulnerable areas, helping maintain crowd control, operating checkpoints, providing humanitarian assistance, and facilitating the rebuilding of infrastructure, all of which can expose peacekeepers to

potentially dangerous and life-threatening situations.

Posttraumatic stress disorder (PTSD)

A psychological disorder that may result from exposure to severe stress and that involves re-experiencing of the traumatic event, avoidance of cues associated with the event, emotional numbing, and hyperarousal symptoms.

Role conflict in peacekeepers

Conflict resulting from exposure to competing demands of neutrality and restraint in the face of life threat or danger, which may lead to feelings of helplessness or frustration.

Rules of engagement

Rules prohibiting use of weapons except in extreme circumstances, which is quite different from ways in which soldiers are traditionally trained to handle provocation and life threat.

Types of Peacekeeping Missions

Peacekeeping has changed considerably following the inception of the United Nations in 1945. There have been 60 peacekeeping missions since 1948, and currently there are 17 active operations throughout the world. Historically, the role of the military in peacekeeping operations has been that of maintaining a strictly neutral presence by overseeing peace accords between formerly warring parties. However, post-Cold War, peacekeepers have shifted to enforcing peace in the midst of active hostilities.

These modern missions have placed peacekeepers into more dangerous and conflict-laden environments. Modern missions require soldiers to be combat trained, yet able to model restraint and maintain neutrality. As a result, peace enforcement is one of the most stressful duties a soldier can be exposed to in the modern military, and the possibility of exposure to traumatic events and death has become even more likely in modern missions. For example, Seet and Burnham found that more deaths have occurred among UN peacekeepers in the past decade than in the previous 40 years, and that deaths from hostile acts have significantly increased following the Cold War.

This article provides brief summaries of the stressors associated with peacekeeping in three different peacekeeping missions, briefly reviews recent peacekeeping missions, summarizes the unique stressors of peacekeeping, and highlights the psychological impact of these missions.

The Multinational Force and Observers in the Sinai

Since the establishment of the state of Israel in 1948, the UN and other multinational organizations have engaged in an ongoing struggle to create and maintain peace between Israel and its neighbors. An example of a very successful attempt to maintain peace in this region is the Multinational Force and Observers (MFO) in the Sinai. Due to the stability of the peace between Israel and Egypt and the receptiveness of both parties to the presence of the MFO, peacekeepers in the Sinai have been exposed to few potentially traumatizing events directly related to their service as peacekeepers. The MFO is an example of a successful peacekeeping mission in which the duty of peacekeepers is strictly to observe, monitor, and report transgressions.

Operation Restore Hope and Operation Continue Hope in Somalia

As a result of the civil war that erupted in Somalia in 1991, humanitarian relief efforts aimed at curbing famine and the spread of disease were interrupted and sabotaged. The UN, with extensive support from the United States, decided to guarantee the provision of humanitarian aid as well as to enforce the peace in Somalia. During this mission, peacekeepers became peace enforcers, and the risk of exposure to potentially traumatic events grew exponentially. Although Operation Restore Hope (ORH) was a great success with regard to the provision of medical and food supplies, the mission is often considered to be a failure because Somalia continues to be at risk for the devastating effects of famine, political instability, and violence.

While in Somalia, U.S. military personnel were assigned to a variety of tasks, ranging from policing

duty to combat-like duty (e.g., patrols, disarming civilians). Peacekeepers were exposed to a fairly well armed civilian population who were actively engaged in interclan war. Peacekeepers in Somalia were also subjected to acts of aggression by some Somalis, yet the strict rules of engagement sharply restricted options for protection or retaliation, creating a general sense of threat.

Operation Joint Endeavor and Operation Joint Guard

In 1991, following the declaration of independence of Slovenia and Croatia, a civil war erupted in the former Yugoslavia. The disillusion of the state gave rise to power struggles over governing control of the remaining states and to old race-based hatreds. Horrible atrocities were perpetrated, including genocidal acts. In response, approximately 60 000 North Atlantic Treaty Organisation (NATO) and U.S. military personnel were deployed as peacekeepers. Peacekeepers in Bosnia-Herzegovina have been subjected to shelling and sniper attacks, and a minority of peacekeepers have also been taken hostage. Some UN peacekeepers have had to stand by helplessly while atrocities were taking place.

Recently Established Peacekeeping Missions

Locations of recent UN peacekeeping missions include (1) Sudan (UNMIS), which began in March 2005 to support implementation of the Comprehensive Peace Agreement, (2) Burundi (ONUB) since May 2004, (3) Haiti (MINUSTAH) since April 2004, (4) Cote D'Ivoire (UNOCI) since February 2004, (5) Liberia (UNMIL) since September 2003, (6) East Timor (UNMISSET) since May 2002, and (7) Ethiopia and Eritrea (UNMEE) since September 2000.

Unique Stressors of Peacekeeping

Peacekeepers are at risk for exposure to stressors that are typical of a war zone (artillery fire, land mines, small arms fire). Even when peacekeepers are tasked with maintaining a firm peace, they are faced with the possibility of life threat. They may be fired upon as a result of a misunderstanding, accidentally in cross-fire between two armed feuding parties, or during firing close, which occurs when the opponent wishes to intimidate the peacekeepers in order to keep them away from a certain area. Peacekeepers may also witness atrocities committed against fellow peacekeepers and civilians and the malicious destruction of property. Other types of stressful experiences for peacekeepers are boredom, isolation, family separation, exhaustion, unfavorable climatic conditions, and demoralization about the mission's efficacy.

Role conflicts may also provoke additional stress in peacekeepers. For combat-trained soldiers from larger nations, peacekeeping duty may feel incongruent with their training. For example, peacekeepers, unlike traditional soldiers, are often restrained from taking offensive action in conditions of life threat. In addition, the types of defensive military structures that are commonplace in war are often not as available on peacekeeping missions due to the proximity that is required in order to provide humanitarian assistance and protection. The emphasis on proximity rather than protection creates considerable hypervigilance and arousal in peacekeepers and contributes to a general sense of fear. Peacekeepers who are unclear about how to respond to threats and/or experience repeated threats of injury, with little or no opportunity for recourse, are likely to experience great anxiety. Furthermore, peacekeepers who are forced to suppress their frustration, fear, and anger are at risk for acting out their feelings during a mission and/or upon their return home.

Psychological Impact of Peacekeeping

Although there are many potentially traumatizing experiences and psychological conflicts associated with being a peacekeeper, the great majority of soldiers appear to adapt well. However, a sizeable number of peacekeepers are at risk for the development of psychopathology related to their deployment. The most frequent mental health problems associated with peacekeeping are PTSD, depression, anger and hostility problems, and alcohol abuse. Mehlum and Weisaeth reported that 7 years following service, 16% of prematurely repatriated soldiers from southern Lebanon met criteria for PTSD. Passey found that more than 20% of the soldiers deployed as peacekeepers to Bosnia endorsed symptoms of PTSD and depression. In Litz and colleagues' examination of U.S. military personnel who deployed to Somalia, 25% of Somalia veterans reported clinically significant psychological distress, particularly hostility and anger problems, and 8% reported clinically significant PTSD; Dirkzwager and colleagues found similar rates of PTSD among peacekeepers who served in Yugoslavia. Among Kosovo peacekeepers, Maguen and colleagues found that 4% endorsed clinically significant PTSD symptoms; Dirkzwager and colleagues found similar rates of PTSD among peacekeepers who served in Cambodia. Gray and colleagues found that although most follow a standard pattern of PTSD development, some peacekeepers exhibit delayed-onset PTSD after a period of minimal distress.

Adler and colleagues examined factors that predicted PTSD in U.S. military personnel deployed to

the Bosnia peacekeeping mission and found that longer deployments and first-time deployments were associated with an increase in distress scores. Interestingly, the association between deployment length and distress was significant only for male soldiers. In a prospective study of Kosovo peacekeepers, Maguen and colleagues found that pre-existing stress symptoms and exposure to stressful war zone events (e.g., going on dangerous patrols) were the most robust predictors of PTSD symptoms. Similarly, in Litz and colleagues' study of Somalia peacekeepers, the extent of exposure to stressful war zone events and frustrations with aspects of the peace enforcement mission (e.g., restrictive rules of engagement) predicted the severity of PTSD. The relationship between war zone exposure and PTSD was strongest for Somalia veterans who had high levels of frustration with the negative aspects of peacekeeping duty. Additional variables associated with PTSD symptoms reported by Dirkzwager and colleagues were feelings of powerlessness and threat, belief that the mission had become meaningless, and lack of control during deployment. Litz and colleagues also found that cohesion and morale during deployment were negatively associated with symptoms of psychological distress and PTSD. On the other hand, Michel and colleagues found that postdeployment adversities most strongly contributed to poor mental health among Swedish peacekeepers that deployed to Bosnia.

Peacekeeping duty can also promote positive outcomes. Dirkzwager and colleagues found that the majority of peacekeepers reported positive consequences of their deployment, with 82% reporting a broadening of their horizon and 52% reporting increased self-confidence. Britt and Adler, and Bartone documented that following deployment to Bosnia, many peacekeepers reported an increase in political understanding, stress tolerance, and professional qualifications. They also found that soldiers who identified more closely with the role of peacekeeper and who believed their assignment to be important were more likely to report a perceived benefit from their peacekeeping experience and were less likely to report burnout and adverse psychological consequences. Finally, the researchers noted that soldiers who reported benefits as a result of the deployment had at least some exposure to the physical damage caused to the local civilians and soldiers from other nations.

Conclusions and Recommendations

Even in the context of conflicts that arise as a result of counterterrorism, peacekeeping and peace enforcement missions will thankfully outnumber wars internationally. Although the psychological casualties

resulting from peacekeeping stress do not compare to combat, it is important to appreciate the mental health needs of soldiers who return from peacekeeping missions, particularly ones that entail unforeseen escalations in hostilities. Peacekeepers may experience a wide range of potentially traumatic events and numerous uniquely stressful experiences. Peacekeeping, especially peace enforcement, missions should include provisions for secondary prevention interventions for those soldiers most at risk for chronic mental health problems following homecoming.

Definition and Classification of Peptides

Biosynthesis and Processing of Peptides: The Proopiomelanocortin Model

Peptide Release

Peptide Receptors

Modulators of Peptide Action

Glossary

Hormone

A peptide, polypeptide, or protein that is released into the circulation via endocrine or exocrine routes to signal to distant tissues.

Neurotransmitter

A compound synthesized and stored within a neuron that, on physiological release into the synapse via a calcium-dependent mechanism, elicits a postsynaptic, receptor-mediated response. Neurotransmitters are also subject to degradation.

Preprohormone

A multipotential precursor protein that contains the amino acid sequence for several different peptides that can be

	liberated with appropriate enzymatic processing; typically, it is inert.
<i>Receptor desensitization</i>	The process by which the repeated stimulation of a receptor with an agonist elicits a smaller response or requires larger doses to achieve a similar response.
<i>Ribosome</i>	The structure outside the nucleus of the cell in which mature mRNA is translated into the coded protein.

Definition and Classification of Peptides

Peptides are generally defined as any member of a class of low-molecular-weight compounds that yield two or more amino acids on hydrolysis. Conversely, peptides also can be defined as any compound produced by amide formation between a carboxyl group (COOH) of one amino acid and an amino group (NH₂) of another, thereby resulting in the loss of water from the adjacent amino acids. Although the word peptide is most often used to refer to compounds in which the amide bonds are formed between C-1 of one amino acid and N-2 of another (or eupeptide bonds), it also applies to compounds with residues linked by other amide bonds (or isopeptide bonds). Because the elements of water are removed from

amino acids in forming peptide bonds, what remains of each amino acid is referred to as an amino acid residue (e.g., glutamic residue instead of glutamic acid). The 21 amino acids known to be encoded genomically and their common abbreviations are listed in [Table 1](#).

Peptides act as signaling agents to transfer information between tissues. Naturally occurring peptides consist of 100 or fewer residues (longer sequences generally are referred to as proteins and have a more complex tertiary structure), making them up to 50 times larger than classic neurotransmitters. Although peptides are found in much lower concentrations than conventional neurotransmitters, their larger size offers a greater capacity for encoding receptor-appropriate structural information, such that peptides can bind with 1000-fold higher affinity and greater selectivity than their smaller transmitter cousins. Peptides generally colocalize with other peptides and transmitting agents, such as classical neurotransmitters and cytokines. The diversity of available chemical messengers greatly increases the permutations of information transfer from a given cell. Peptides are thought to represent an evolutionarily older class of transmitter than the biogenic amines, with peptides having their roots in hormonal function. More than 70 peptides

Table 1 Amino acids and their symbols

<i>Amino acid</i>	<i>One-letter symbol</i>	<i>Three-letter symbol</i>	<i>DNA codons</i>
Alanine	A	Ala	GCT, GCC, GCA, GCG
Aspartic acid or asparagine ^b	B	Asx	See specific entries
Cysteine	C	Cys	TGT, TGC
Aspartic acid	D	Asp	GAT, GAC
Glutamic acid	E	Glu	GAA, GAG
Phenylalanine	F	Phe	TTT, TTC
Glycine	G	Gly	GGT, GGC, GGA, GGG
Histidine	H	His	CAT, CAC
Isoleucine	I	Ile	ATT, ATC, ATA
Lysine	K	Lys	AAA, AAG
Leucine	L	Leu	CTT, CTC, CTA, CTG, TTA, TTG
Methionine	M	Met	ATG
Asparagine	N	Asn	AAT, AAC
Proline	P	Pro	CCT, CCC, CCA, CCG
Glutamine	Q	Gln	CAA, CAG
Arginine	R	Arg	CGT, CGC, CGA, CGG, AGA, AGG
Serine	S	Ser	TCT, TCC, TCA, TCG, AGT, AGC
Threonine	T	Thr	ACT, ACC, ACA, ACG
Selenocysteine	U	Sec	Specific in-frame TGA codons ^a
Valine	V	Val	GTT, GTC, GTA, GTG
Tryptophan	W	Trp	TGG
Tyrosine	Y	Tyr	TAT, TAC
Glutamic acid or glutamine ^b	Z	Glx	See specific entries
Unknown/Other	X	Xaa	—

^a Although TGA also functions as a stop codon, it is now recognized that certain in-frame TGA nucleotide sequences conditionally direct the incorporation of selenium as selenocysteine, the twenty-first amino acid.

^b Used when identity is ambiguous. Once identity is confirmed, the appropriate amino acid-specific symbol is used. For glutamic acid/ glutamine (Z, Glx), the symbols also refer to any substance that yields glutamic acid on acid hydrolysis of the peptide.

have been identified in neural tissue, many in extra-hypothalamic tissue, where they act locally as neurotransmitters, neuromodulators, or trophic factors. Possibly related to their evolutionary history, many peptides have a longer duration of action than their amine counterparts. Thus, some have been described as modulating the tone of the information circuits over long time intervals. In other instances, the neuromodulatory action of peptides is to tune the gain of circuits in response to fast-acting, classic synaptic transmitters such as glutamate or γ -aminobutyric acid. Nevertheless, some peptides that meet the conventional criteria for neurotransmitters also signal information more dynamically. Although there is no consensus regarding a classification system for peptides, one approach has been to divide them according to their major anatomical location and effector mechanism. According to this scheme, biologically active peptides can be divided into the following classes: (1) gut peptides and central nervous system (CNS) neuropeptides, (2) hypothalamic neuropeptides that control the release of anterior pituitary hormones via a neurohormonal route, and (3) pituitary peptides that act primarily as hormones. Although this classification served a heuristic purpose, most peptides or homologous peptide gene products (e.g., gonadotropin-releasing hormone (GnRH) I and II and urocortins 1, 2, and 3) and their putative cognate receptors were subsequently identified in tissues other than those in which they were originally identified, in many cases acting in autocrine or paracrine, rather than endocrine, fashion. These tissues include the muscle; lungs; heart; adipose tissue; skin; and glial, immune, and hematopoietic cells and indicate the functional diversity of peptide action.

Biosynthesis and Processing of Peptides: The Proopiomelanocortin Model

Unlike biogenic amines, which are produced nonribosomally by biosynthetic enzymes, neuropeptides and hormones are derived from larger, mostly inactive precursor molecules that are gene products. Bioactive peptides are enzymatically cleaved and stored from these multipotential precursors. The biosynthesis and processing of one such precursor – proopiomelanocortin (POMC), the prohormone for adrenocorticotrophic hormone (ACTH), melanocyte-stimulating

hormone (MSH), lipotrophic hormone (LPH), and several opioids – has been well characterized and serves as a useful model for understanding the production of peptides *in vivo*. The POMC gene was the first neuropeptide precursor gene to be cloned and, like most peptide genes, has been found to be organized similarly across mammalian species. Spanning 6 kb, the POMC gene comprises three exons and two introns (see Figure 1). Upon transport from the nucleus to the cytoplasm, functional, mature POMC mRNA transcripts span 1100–1400 nt due to tissue-specific differences in the degree of 3' polyadenylation of the mRNA. Transcripts subsequently bind to free ribosomes, where the translation of the N-terminus of the preprohormone begins. Exon 2 of the POMC gene codes for a 26-amino-acid signal (pre)peptide characteristic of all known secretory proteins. The binding of this α -helical signal peptide to a signal-recognition ribonucleoprotein and the association of this complex to a docking protein on the rough endoplasmic reticulum (RER) is required for further translation of peptide precursors. Once in the RER, the signal peptide is removed and the translation of the prohormone is completed. As can be seen in Figure 2, the translated POMC prohormone contains a multipotential N-terminal domain that contains the sequence for γ -MSH, a joining peptide, and domains that contain the full sequences for ACTH and β -lipotropin. From this point on, the prohormone undergoes posttranslational processing in a biologically regulated and tissue-specific manner to yield tissue- and state-specific peptide cocktails ready to be released from secretory vesicles. As can be seen in Figure 2, a multitude of peptides could be cleaved from this hormone, depending on physiological demands. Adding yet further flexibility to the system, certain peptide sequences are contained in multiple prohormones (e.g., met-enkephalin is present in both POMC and preproenkephalin). Much of this processing involves proteolytic cleavage by convertases at sites distal to dibasic residues (Arg-Lys, Lys-Arg, Lys-Lys) that flank the desired peptide sequence. For some peptides, a single basic residue (Arg) serves as the cleavage signal. Subsequently, the flanking dibasic peptides are snipped from the target peptide by carboxypeptidases. En route from the RER to the smooth endoplasmic reticulum, the Golgi apparatus and, ultimately, the secretory granules, the prohormone, and its peptide derivatives are also subject

Figure 1 Representation of the structure of the rat proopiomelanocortin (POMC) gene.

Figure 2 Representation of the structure of the bovine preproopiomelanocortin prohormone. The locations of known peptide components are shown in closed boxes with the amino acid numbers in parentheses. Paired basic amino acid residues (Arg-Lys, Lys-Arg, and Lys-Lys) and single cysteine residues, which represent possible cleavage sites, are marked with vertical bars. to several enzymatic nonproteolytic modifications, including glycosylation, deglycosylation, acetylation, sulfation, phosphorylation, carboxymethylation, and C-terminal amidation. These modifications facilitate transport or storage, increase metabolic stability, and alter the product's bioactivity (e.g., the importance of C-terminal amidation for many peptides or of Ser3-acetylation for ghrelin). Thus, the process by which a particular peptide or peptide cocktail is localized in a secretory granule is extremely complex, with regulation (or dysregulation) possible at the level of prohormone synthesis, enzymatic processing, transport, and storage.

Peptide Release

Some peptides, notably growth factors, follow a constitutive route of release whereby they proceed directly from the Golgi network to the cell surface, bypassing storage in secretory granules. More typical of stress-related peptides found in endocrine cells and neurons, however, is a regulated route of release, as described in the POMC model, whereby the peptide is packaged in large, dense, core secretory vesicles until liberated by the appropriate stimulation of the cell. Neuropeptide release, like that of biogenic amine neurotransmitters, is induced by cell depolarization in a calcium-dependent manner. However, unlike bioamines, which are released from smaller clear synaptic vesicles during low-frequency activity, neuropeptides are generally released from large, dense core vesicles only on high-frequency burst firing. Because peptides lack reuptake sites to replenish secretory stores, *de novo* synthesis of new peptide is the major mechanism for replacement after release, such that peptide release can often be inferred indirectly from a compensatory increase in peptide mRNA expression.

Peptide Receptors

Once released, peptide ligands must interact with their receptors to transmit information. Neuropeptide receptors are generally expressed at low densities (1–10 pmol/mg protein at highest concentrations). Prior to the advent of molecular biological techniques, this made them difficult to isolate, clone, and characterize, although much recent progress has been made. They have been observed both pre- and postsynaptically on the soma, axons, and dendrites of neurons, indicating a complex mode of communication.

G-protein-coupled receptors

With few exceptions, peptide receptors are guanine nucleotide-binding (G)-protein-coupled receptors (GPCRs). The G-protein-coupled superfamily of receptors, which represents approximately 80% of all known receptors, has a highly conserved domain structure, with seven predicted transmembrane α -helices. The hydrophobic transmembrane core regions show the greatest homology across peptide receptors, whereas variation in the intra- and extracellular domains yields the diversity of receptor families and subtypes. A conserved, paired acid–base residue at the base of the third transmembrane appears to play a role in G-protein activation. The full range of nonphotorceptor G-protein-mediated signal transduction mechanisms has been described for these receptors, including the positive and negative regulation of adenylyl cyclase, stimulation of phospholipase C, and positive and negative regulation of ion channels (Ca^{2+} , K^{+} , and nonselective $\text{Na}^{+}/\text{K}^{+}$). Of approximately 360 GPCRs coded in the human genome and identified in a database maintained by the International Union of Pharmacology Basic and Clinical Pharmacology Committee on Receptor Nomenclature and

Drug Classification, approximately one-fourth are known to have peptide ligands. Of peptide GPCRs, approximately 70 belong to the largest family, the class A or rhodopsinlike receptors; 15 belong to the class B (secretinlike) family of receptors for large polypeptidelike hormones; and none belong to the class C receptor family. A further 70 orphan GPCRs are estimated to have peptide ligands.

A few peptide receptors belong to the guanylate cyclase (rather than GPCR) family of membrane receptors. Ligands for these receptors, which are single-transmembrane proteins that regulate intracellular cyclic guanine monophosphate (cGMP) accumulation, include atrial natriuretic peptide, C-type natriuretic peptide, uroguanylin, and guanylin. Finally, a very limited number of peptides bind to other receptor types, including an ionotropic receptor for an invertebrate tetrapeptide FMFRamide and sortilin, a large, single-transmembrane receptor for neurotensin that has a long extracellular domain.

Theories of Peptide–Receptor Interaction

Peptides' activation of receptors cannot be explained by a simple lock-and-key model of amine–receptor interaction. Rather, two heuristic models, although theoretical, provide a framework for understanding peptide–receptor interactions: a zipper model and an address–message model. The former emphasizes that the association of a single amino acid on the peptide to a complementary receptor binding site initiates a series of interactions that results in a receptor-bound activating confirmation. The latter notes that certain portions of the peptide (the address) are more important for binding the ligand with the receptor, whereas other portions (the message) are more important for initiating the conformational changes in the receptor that lead to signal transduction. Many, if not most, peptide receptors also exhibit a state of constitutive activation in the absence of ligand. Like their ligands, peptide receptors undergo posttranslational processing, including alternative splicing and differential N-glycosylation and phosphorylation. These modifications, which alter receptor binding affinities and signal-transduction efficiency, form the basis of several receptor subtypes.

Desensitization and Regulation of Peptide Receptors

Many peptide receptors, like their amine counterparts, undergo rapid-onset (<30 min) homologous receptor desensitization. The C-terminal tail of the receptor appears to participate in this process, perhaps by modifying intracellular protein interactions. Some

receptors also exhibit heterologous augmentation of homologous desensitization; for example, arginine vasopressin synergistically enhances corticotropin-releasing factor (CRF)-induced desensitization of CRF receptors. However, the mechanism for this process is unclear. Finally, peptide receptor synthesis and expression also are subject to homologous and heterologous regulation.

Modulators of Peptide Action

Unlike biogenic amines, whose actions are terminated in part by cellular reuptake, peptide action is modulated by two specific largely extracellular mechanisms – peptidases and peptide-binding proteins.

Peptidases

Proteases are enzymes encoded by 2% of genes in all living organisms that hydrolyze peptide bonds, potentially with ensuing functional consequences. Proteases can be classified as the somewhat more common endopeptidases, which cleave at internal residues, or as exopeptidases, which break terminal peptide bonds. Exopeptidases are further subclassified into aminopeptidases and carboxypeptidases, according to their localized site of action. Proteases also can be described according to their chemical site of action (e.g., cysteine, serine, or threonine proteases). Peptidases exhibit varying degrees of substrate specificity, with few exhibiting high selectivity (e.g., the thyrotropin-releasing hormone-degrading ectoenzyme specifically inactivates thyrotropin-releasing hormone). Many peptidases, such as endopeptidase 24.11, angiotensin-converting enzyme, and pyroglutamate aminopeptidase II, are synaptosomally located, poised to limit neurotransmission by inactivating peptides released into the synaptic cleft. Indeed, peptidase release appears to be induced by neuronal depolarization. Other peptidases, however, such as aminopeptidases A and M, dipeptidyl aminopeptidase IV, and carboxypeptidase, appear to be located in the microvasculature and to be situated to limit volume transmission, or signaling occurring over a great distance, as well as to limit passage across the blood–brain barrier. A third class of membrane-associated cytoplasmic peptidases in the neural and glial tissue, for example, pyroglutamyl peptidase I, also may help to inactivate the released peptide. Finally, receptor-mediated endocytosis, with subsequent lysosomal degradation, is an additional route of limiting peptide activity. Each peptide is subject to inactivation by a variety of peptidases, with each reaction yielding different metabolic products. Because many of these metabolic products can act as agonists

or antagonists (in a manner sometimes functionally distinct from those of the parent peptide – for example, the conversion of peptide YY to peptide YY_{3–36}), the physiological control of bioavailable peptidases is an additional important determinant of peptide action. Protease activity is regulated *in vivo* by endogenous inhibitors, zymogen activation, and the modulation of their synthesis or degradation. Because of peptidases, natural peptides generally have very short half-lives (on the order of minutes) *in vivo*. Peptides with deletions, unnatural amino acids, or substitutions that eliminate a natural cleavage site can result in compounds with greater metabolic stability. Depending on the specific intrinsic activity of the analog, it could then function as a long-acting antagonist (e.g., astressin-B compared to corticotropin-releasing factor), an agonist (exendin-4 compared to glucagon-like peptide-1) or an inhibitory superagonist ([D-Trp⁶, Pro⁹-NET]-GnRH compared to GnRH). Similarly, inhibitors of peptidase action can augment or prolong peptide action. The MEROPS database maintains an integrated list of known peptidases and peptidase inhibitors classified according to their structural similarity or catalytic site of action.

Peptide-Binding Proteins

Peptide-binding proteins are soluble or membrane-bound proteins to which peptides bind in lieu of their cognate receptor. Often, they act to sequester peptide ligands, thereby limiting their bioavailability (e.g., CRF-binding protein). Some binding proteins (e.g., insulin-like growth factor-binding protein), however, potentiate peptide action by protecting peptides from extracellular peptidases and forming a bound complex that associates with the membrane, thereby facilitating peptide–receptor interaction. Binding proteins are physiologically regulated through enzymatic modifications of their affinity for the peptide ligand or through changes in synthesis and expression, with consequent effects on peptidergic activity.

Glossary

Dexamethasone
Early life programming

A synthetic fluorinated glucocorticoid hormone structurally related to cortisol. Programming reflects the action of a factor during a sensitive developmental period, or time window, to affect the development and organization of specific tissues that are concurrently vulnerable, producing effects that persist throughout life. Different cells and tissues are sensitive at different times, so the effects of environmental challenges will have distinct effects, depending not only on the challenge involved but also on its timing.

Early Life Programming

Lifestyle and genetic predisposition are considered to be the main determinants of noncommunicable diseases in humans. However, increasing evidence from studies in several distinct human populations worldwide indicates that many disorders occurring in adult life date back to influences of the intrauterine environment during the prenatal period. Examples of illnesses for which there is evidence of fetal origin are hypertension, coronary heart disease, diabetes, and neurological disorders. Behavioral disorders during childhood and adolescence may also be programmed during the prenatal period. As it is generally accepted that a multitude of pre- and postnatal influences are involved in pathophysiological processes that predispose individuals to such diseases, it is plausible to propose that there are factors triggering fetal

development, thus amplifying or minimizing certain long-term processes. One identified trigger is hormonal disturbance such as high glucocorticoid exposure during pregnancy. However, most of the studies in humans have been restricted to either epidemiological or some physiological measurements that in sum cannot explain the cause and basic mechanisms underlying the pathophysiological processes.

A high percentage of pregnant women with an increased risk of preterm delivery are treated with glucocorticoids for enhancement of fetal lung maturation before term. The underlying mechanism for why this treatment is used in fetal pulmonary development is the ability of glucocorticoids to turn off cell proliferation and initiate mature cell function. In addition to being used in cases of preterm labor, synthetic glucocorticoids are administered to pregnant women in other clinical situations, including congenital adrenal hyperplasia and a wide spectrum of autoimmune disorders such as multiple sclerosis, asthma, rheumatic diseases, or chronic inflammatory intestinal diseases (M. Crohn, colitis ulcerosa). Often these treatments occur in early pregnancy, when it has not yet been diagnosed, and in some cases throughout gestation. There is currently little information about the impact of such treatment regimes on organ development. Epidemiological data indicate that fetuses exposed to synthetic glucocorticoids such as dexamethasone display significant increases in emotionality, unsociability, and behavioral problems in later life as children. However, further resolution of the safety of these treatment regimes is urgently needed. As a result, two National Institutes of Health (NIH) consensus reports published in 1995 and 2001 suggested that repeated or prolonged treatment should be avoided during pregnancy and highlighted the requirement for further research on the effects of prenatal glucocorticoids on organ development and function after birth.

Dexamethasone: Actions and Potencies

Synthetic glucocorticoids were developed by modifying various sites on the cortisol molecule in order to, for example, enhance the anti-inflammatory and reduce the Na^+ -retaining mineralocorticoid activity. Among synthetic agents, the fluorinated steroid dexamethasone (DEX) has the lowest mineralocorticoid effect; it is characterized by a very long half-life, with the consequence of a greater potential to cause glucocorticoid-related side effects. DEX can be administered orally and, as with other steroids, is rapidly absorbed from the jejunum with high bioavailability,

Table 1 Comparative potencies of cortisol and dexamethasone

	Equivalent dose (mg)	Plasma half-life (min)	Duration of action (h)	Mineralocorticoid potency	Glucocorticoid potency	Relative placental inactivation (% of drug inactivated)
Cortisol	20	90	8–12	1	1	68
Dexamethasone	0.5	240	36–72	0	30	2

From Lin and Paget (2002).

meaning that up to 90% of an orally administered dose appears in the circulation, although bioavailability after oral administration is less than after parenteral administration because of substantial first-pass liver metabolism (Table 1).

DEX is used in the differential diagnosis of hypercortisolemia as it occurs, for example, in Cushing's disease, atypical pituitary adenomas, or depression (see **Hypocortisolism and Stress**). In this context, it is interesting to note that at least the adult rodent brain appears to be protected against high amounts of DEX by a multidrug-resistant P-glycoprotein located in the blood–brain barrier.

Placental Metabolism of Glucocorticoids

Transplacental passage of the different corticosteroid molecules varies, so different substances have to be used for maternal than for fetal targets. Dexamethasone and betamethasone, a second member of the clinically used fluorinated glucocorticoids, cross the placenta more readily than the natural glucocorticoid cortisol does because they are not bound to transporter proteins in the maternal blood, nor are they as easily converted to cortisone by placental enzymes such as 11 β -hydroxysteroid dehydrogenase (11 β -HSD). The relative inactivation of various corticosteroids to their 11-ketometabolites, through action of placental 11 β -HSD, ranges from 2% (DEX) to 68% (cortisol; see Table 1). Within the placenta, two isoforms of 11 β -HSD exist: a low-affinity NADP-dependent dehydrogenase/oxoreductase and a high affinity NAD-dependent dehydrogenase. Expression and distribution of these isoforms within the placenta most likely have an impact on levels of active glucocorticoids in fetal blood so that a complex interplay of factors determines the degree of fetal exposition.

Dexamethasone and Fetal Development

The assumption that excessive fetal exposure to glucocorticoid hormones constitutes an origin of adult diseases is based on studies in experimental animals. Findings in laboratory rodents (mice, rats, guinea pigs) concur with observations in ruminants and monkeys, mainly rhesus monkeys, documenting many lasting endocrine, neural, and behavioral effects when

immature animals are exposed to steroidal hormones early in life. To model perinatal hyperexposure to glucocorticoids under controlled conditions, many research groups have studied the *in utero* effects of DEX, whose cellular effects are mediated via the glucocorticoid receptors (GRs) that are present in nearly all cells of the body (see **Glucocorticoids, Effects of Stress on**). It is known that synergistic and/or antagonistic interactions between activated GRs and several transcription factors regulate gene expression. Many organs, such as the brain, and the cardiovascular, skeletal, immune, reproductive, and urogenital systems contain cells that are vulnerable to changes in glucocorticoid homeostasis, and it is very likely that excess antenatal glucocorticoids such as DEX have multiple pathophysiological effects. The developmental consequences of prenatal DEX treatment are summarized in Figure 1.

Animal studies have revealed that, via the effects on gene transcription, glucocorticoids exert well-documented prenatal programming actions in a variety of target tissues to induce effects that may persist throughout the life span. For example, the adult rat offspring of pregnancies treated with DEX exhibited lifelong elevated blood pressure and high levels of plasma glucose, insulin, and corticosterone, as well as altered behavior. Variations in the effectiveness of the fetoplacental enzymatic barrier to maternal glucocorticoids because of changes in 11 β -hydroxysteroid dehydrogenase type 2 (11 β -HSD2), which catalyzes the rapid inactivation of cortisol (or corticosterone in rats) to inert cortisone (11-dehydrocorticosterone), correlate directly with birth weight in rats and humans. Thus, a deficiency of the placental barrier with respect to inactivation of maternal glucocorticoids, or overexposure to the hormones, may lead to increased effects of the hormones on gene expression in the fetal cells, and thus to prenatal programming. This idea is supported by the finding that, comparable to the effects of DEX, inhibition of 11 β -HSD in pregnant rats by treating them with carbenoxolone causes reduced birth weight and hypertension later in life. Interestingly, the effects of carbenoxolone require the presence of endogenous maternal glucocorticoids: the offspring of adrenalectomized pregnant rats were found to be protected from the effects of carbenoxolone with respect to birth weight and adult physiology. However, it has

Figure 1 Developmental consequences of prenatal dexamethasone treatment. Fetal dexamethasone overexposure in combination with genetic and environmental factors will influence the development of many organ systems and programs tissue responses in the developing offspring, resulting in an increased risk for pathophysiological conditions later in life.

to be considered that carbenoxolone is a nonselective compound that inhibits both 11β -HSD isoforms as well as related dehydrogenases.

The timing of antenatal glucocorticoid exposure is important, in part because of the complex species-specific patterns of expression of the 11β -HSD isoenzymes that regulate maternal glucocorticoid transfer to the fetus. In rats, exposure to glucocorticoids during the last week of pregnancy is sufficient to produce permanent adult hypertension, whereas in sheep, the time window of sensitivity for such effects is earlier in gestation.

Mice and rats have been regarded as corticoid-sensitive species because their newborn pups are extremely immature at birth. Therefore, the relevance of rodent models of prenatal glucocorticoid overexposure has sometimes been questioned. However, similar types of adverse effects have also been observed in sheep, including an influence of physical growth and suppression of maternal and fetal adrenal activity. These glucocorticoid effects in sheep are surprising because high maternal cortisol levels play an important role in the normal physiology of their pregnancy and parturition. It is possible that in certain species the fetus is typically protected from excessive transplacental diffusion of cortisol/corticosterone through the enzyme 11β -HSD.

In monkeys, the natural ligand cortisol is metabolized even more rapidly in the fetus than in the full-term neonate. Conversely, DEX takes considerably longer to clear from the circulation. This extended half-life may be important when DEX is administered to the mother while the baby is still *in utero* and thus depends on the transfer of steroid hormones back across the placenta, rather than on its own renal excretion after birth.

Unfortunately, not enough animal studies have been conducted with betamethasone to permit a systematic comparison with DEX. In general, the research in humans tends to find more side effects with DEX than with betamethasone.

Metabolic Programming

The preceding findings imply that glucocorticoids exert organizational effects on the immature system during defined developmental stages, leading to changes in physiology that have persistent consequences throughout the lifetime. Because reduced prenatal growth and low birth weight are determined largely by nongenetic factors, these findings have led to the fetal origin hypothesis. It proposes that the physiology of the fetus adapts to the adverse intrauterine environment, which in turn reduces fetal growth

and programs the lifelong changes. This programming predisposes an individual to the metabolic syndrome that manifests itself only in adulthood. It emanates from a general disturbance of the body's metabolic processes and leads to heart disease, diabetes, and kidney failure. These illnesses have long been observed as being somehow linked to modern civilization, but the fact that they constitute an entire syndrome has been recognized only recently.

Blood Pressure

The impact of prenatal glucocorticoid exposure during development on arterial blood pressure has been investigated in the offspring of several species. Treatment of pregnant rats with DEX results in persistent elevations of arterial blood pressure in the adult offspring. Maternal administration of the 11 β -HSD inhibitor carbenoxolone leads to elevated blood pressure in the adult offspring. As previously mentioned, this effect requires the presence of maternal glucocorticoids, as the offspring of adrenalectomized pregnant rats are protected from the adverse actions of carbenoxolone.

The mechanisms of glucocorticoid-programmed adult hypertension are not clearly understood but probably involve a variety of processes. Potential factors may involve primary effects on the heart by interfering with the development of cardiac noradrenergic innervation, modifications in vascular responsiveness, alterations in renal structure (irreversible reductions in nephron number), and enhanced activity of the renin-angiotensin system.

Glucose Homeostasis

Prenatal overexposure to glucocorticoids also causes permanent hyperglycemia and hyperinsulinemia in the adult offspring of rats and sheep. As with blood pressure, the window of sensitivity for programming hyperglycemia in the rat occurs in the last third of gestation. Earlier DEX exposure or *post partum* treatments do not program hyperglycemia/hyperinsulinemia, suggesting that there is a narrow window for this effect. The mechanisms through which prenatal superphysiological levels of glucocorticoids program hyperglycemia have not been fully determined but may involve derangements in several target organs such as the liver, the pancreas, fat, and skeletal muscle.

Glucocorticoids regulate the expression of several hepatic metabolic enzymes, including phosphoenolpyruvate carboxykinase (PEPCK). This enzyme develops in late gestation and catalyzes a rate-limiting step in gluconeogenesis. In rats, exposure to excess DEX *in utero* leads to offspring with permanent elevations in PEPCK mRNA and enzyme activity. Interestingly the PEPCK activity is increased in patients with type 2 diabetes.

Relatively little is known about the effects of prenatal exposure to glucocorticoids on the development of the endocrine functions of the pancreas. However, indirect evidence suggests that excessive prenatal glucocorticoid levels may cause long-term beta cell dysfunction.

Prenatal DEX exposure in rats programs fat metabolism. Adult offspring of dams exposed to DEX in pregnancy have increased intra-abdominal fat depots, with a parallel increase in leptin levels. The same antenatal treatment may also affect skeletal muscle glucose metabolism.

Effects on Brain, Endocrine, and Immune Functioning and Behavior

In addition to their metabolic role, glucocorticoids are essential for normal brain development. Glucocorticoids are important for normal maturation in most regions of the developing central nervous system, initiating terminal maturation and remodeling axons and dendrites, and for cell survival.

Exposure to glucocorticoids *in utero* has widespread acute effects on neuronal structure and synapse formation and may permanently alter brain structure. Prenatal glucocorticoid administration retards brain weight at birth in sheep, delaying maturation of neurons, myelination, glia, and vasculature. Rhesus monkeys that were prenatally exposed to DEX exhibited marked atrophy of hippocampal cells at birth, and their hippocampi failed to recover to normal size, even at 2 years *post partum*. Human and animal studies have demonstrated that altered hippocampal structure may be associated with memory impairment and behavioral alterations (see **Hippocampus, Corticosteroid Effects on**).

Overall, the development of the hippocampus in rhesus monkeys is comparable to that in humans, although it is difficult to specifically compare the rate of fetal growth and stage of maturity at birth. However, in humans, important phases in maturation of the brain, including brain growth, take place during the postpartum period. At birth, the brain of a rhesus monkey is 60% of its adult size, whereas the human brain is only 24% of its adult size. Thus, the impact of prenatal DEX overexposure on the developing nervous system may be of a greater magnitude in the monkey.

The hypothalamic-pituitary-adrenocortical (HPA) circuit, which is central for the integration of an individual's endocrine and behavioral responses and for the whole body's homeostasis, appears highly sensitive to excess glucocorticoids during development. A number of animal studies have shown that exposure to synthetic glucocorticoids *in utero* results in disturbed hypothalamic-pituitary circuit functioning.

Studies in rats provided evidence that perinatal DEX treatment enhances susceptibility to experimental autoimmune encephalitis (EAE) in adult life. EAE is an experimental autoimmune inflammatory disease that serves as an animal model for multiple sclerosis. Low reactivity of the HPA axis and increased Th1-type cytokine production are discussed as potential mechanisms for this increased susceptibility in adult rats after DEX treatment. Furthermore, perinatally DEX-treated rats have a long-term decreased production of cytokines by macrophages. This may lead to increased susceptibility to bacterial infections in later life. Apparently, perinatal DEX treatment has permanent programming effects on endocrine as well as on immune functioning in adult life.

As revealed mainly by studies in rats, overexposure to glucocorticoids *in utero* leads to alterations in adult behavior. Late gestational DEX in rats apparently impairs coping in aversive situations later in life. Behavioral changes in adult rats exposed prenatally to glucocorticoids may be associated with altered functioning of the amygdala, a key brain structure in the regulation of fear and anxiety. Interestingly, in rats, adult offspring of DEX-treated dams show increased corticotropin-releasing hormone levels, specifically in the central nucleus of the amygdala.

Intergenerational Effects of Dexamethasone

The effects of fetal programming may not be limited to the first-generation offspring. A recent study investigated epigenetic effects in the DEX-programmed rat, a model in which fetal exposure to excess corticosteroids results in low birth weight, adult glucose intolerance, and increased activity of the key hepatic gluconeogenic enzyme PEPCK. Male offspring of female rats that had been exposed prenatally to DEX, but that were not treated during their pregnancy, also had reduced birth weight, glucose intolerance, and elevated hepatic PEPCK activity. These effects resolved in a third generation. Similar lifelong programming was observed in the offspring of male rats exposed prenatally to DEX mated with control females. The persistence of such programming effects across several generations, transmitted by either maternal or paternal lines, indicates – at least in rodents – the potential importance of non-genomic factors in the intergenerational inheritance of the programming phenotype.

The Underlying Mechanism: A Permanent Alteration of Gene Expression?

The GR is critical for cell function, and GR gene expression shows marked tissue-specific regulation. In the peripheral tissues, such as the liver and visceral

adipose tissue, prenatal glucocorticoid exposure causes a permanent increase in GR expression; this upregulation is paralleled by increased glucocorticoid sensitivity in these tissues.

Until recently it was unclear how perinatal glucocorticoid overexposure could permanently alter gene expression. Recent evidence suggests that this priming may involve selective methylation/demethylation processes of specific promoters of the GR gene. Changes in the GR promoter DNA methylation pattern were associated with altered histone acetylation and transcription factor (NGFI-A) binding to the GR promoter. Treatment of the adult rat offspring with a histone deacetylase inhibitor removed the epigenetic differences in histone acetylation and DNA methylation and changes in NGFI-A binding. During development, such target promoter demethylation occurs before birth and may tune the promoter to remember regulatory events occurring during development. This novel mechanism of gene control by environmental events early in life, which then persists throughout the life span, needs to be confirmed in species other than rodents.

Conclusions

Balanced levels of glucocorticoids are of central importance for normal development, and it can be assumed that glucocorticoid overexposure during critical periods of fetal development may have long-term effects that could be deleterious later in life. To date, most of the studies in humans have been restricted to either epidemiological or some physiological measurements that in sum cannot explain the cause and basic mechanisms underlying the pathophysiological processes. In contrast, animal studies have indicated a link between glucocorticoid overexposure and an increased risk for pathophysiological conditions later in life. Until now, experimental studies on the mechanisms induced by prenatal hyperexposure to glucocorticoids such as DEX have been conducted predominantly in rodents. However, rodents are far from ideal models of primate pregnancy due to their multiple offspring and short gestation lengths and life span. Clearly, mechanistic studies need to be extended to species more closely related to humans.

Health Risks of the Gulf War

Mental Health

Predictors of Posttraumatic Stress Disorder

Physical Symptoms in Gulf War Veterans

Relationship between Physical and Psychological
Complaints

Summary

Glossary

*Posttraumatic
stress disorder
(PTSD)*

This disorder results from situations in which an individual believes that he or she or someone else is in danger of being seriously injured or killed. Symptoms of PTSD include repetitive re-experiencing of the trauma in the form of intrusive memories, nightmares, and flashbacks; persistent avoidance of stimuli reminiscent of the trauma; a general numbing of emotions; and increased arousal as expressed by hypervigilance, exaggerated startle, irritability, and insomnia.

Health Risks of the Gulf War

In 1990 the United States and allied countries responded to the Iraqi invasion of Kuwait by deploying

a large number of soldiers to the Persian Gulf. Operation Desert Storm began in 1991 when Allied forces launched a 5-week intensive air attack on Iraq. This was followed by a 4-day ground war. The number of deaths to American and Allied forces during the Gulf war was limited compared to World War I and II, the Korean war, and the Vietnam war. Nevertheless, since the end of the Gulf war, a substantial number of Desert Storm veterans have experienced a host of physical and psychological symptoms that, in some cases, have had a pronounced impact on psychosocial functioning.

Military personnel stationed in the Gulf were exposed to a wide variety of potential health risks. These included a hostile environment (e.g., extreme temperatures, humidity and rainfall, blowing sand, crowded living conditions), infectious agents (e.g., leishmaniasis, sandfly fever), medical prophylaxis (e.g., pyridostigmine bromide, anthrax, and botulinum toxin vaccines), occupational exposures (e.g., chemical exposures associated with routine maintenance and repair of equipment, fuels), environmental hazards (e.g., pesticides, smoke from oil well fires), depleted uranium (used in some artillery shells), the possibility of chemical and biological warfare agents (e.g., organophosphate nerve agents, sulfur mustard, anthrax, botulinus toxin), and repetitive physiological and psychological stress.

Soldiers serving in the Persian Gulf were exposed to numerous potential psychosocial stressors. Stressors associated with deployment included uncertainty about parameters of deployment (e.g., the period of waiting for deployment, unknown length of tour and return date), overestimation of Iraqi military forces, media anticipation of high casualty rates, and separation from home and family. As in all wars, soldiers described the anticipation of combat as being highly stressful. In a study of 1524 deployed military personnel, 80% of subjects reported feeling stressed by the persistent threat of SCUD missile attacks, terrorist attacks, and biological and chemical warfare. Many experienced strong emotional responses to repeated missile warnings and the rapid donning of protective gear that they did not fully trust would be effective against all possible toxic agents.

Reports of directly experienced traumatic events vary depending on the units studied. A series of scientific investigations commissioned by the U.S. Department of Defense found that 40% of soldiers in the units studied experienced incoming indirect fire, between 40 and 70% reported exposure to mines and booby traps, 40% in two units recalled firing rounds at the enemy, and 80% in one unit and 60% in another claimed to see enemy killed or wounded in action. In two units more than 20% of soldiers believed they were in imminent danger of being killed at some point during their tour in the Persian Gulf.

Reports of seeing an American wounded by friendly fire had great emotional impact, as did work in grave registration units. Sadly, some traumas experienced in the Gulf, such as sexual harassment and assault, were inflicted by Americans on their own fellow soldiers.

Other frequently cited Gulf war stressors include austere physical environment and severe climatic conditions, heavy workload, sleep deprivation, inadequate supplies and equipment, lack of information, poor leadership and unit morale, and unsatisfactory living conditions.

Mental Health

The psychological consequences of war have been described for centuries and have been referred to by a variety of different terms, including shell shock, irritable heart of soldiers, physioneurosis, and, most recently, posttraumatic stress disorder (PTSD). PTSD results from situations in which the individual believes that he or she or someone else is in danger of being seriously injured or killed. Symptoms of PTSD include repetitive re-experiencing of the trauma in the form of intrusive memories, nightmares, and flashbacks; persistent avoidance of stimuli reminiscent of the trauma; a general numbing of emotions; and increased arousal as expressed by hypervigilance, exaggerated startle, irritability, and insomnia. Depression, anxiety, substance use, and changes in personality traits are other frequently cited consequences of trauma.

Psychological Symptoms in Persian Gulf Veterans

Prior to the ground war it was estimated that acute psychiatric casualties might reach as high as 50 000. This estimate was based on experience from previous wars. However, during the Gulf war there appeared to be very few psychiatric casualties. Between August 1990 and August 1991, 476 soldiers were evacuated from southwest Asia for psychiatric reasons. This number constituted only 6.5% of all medical evacuations from the Persian Gulf. Similarly, only 158 soldiers from the U.S. Army 7th Corps received mental health treatment while stationed in the Gulf, and 99% were returned to duty after brief treatment. These low rates led to the belief that psychiatric problems in Gulf veterans would be lower than expected. Explanations for low rates included the brief nature and success of the war, limited exposure to traditional combat stressors, and high levels of perceived social support.

Since the end of the Gulf war, however, a number of different research groups have reported rates of psychiatric symptoms and disorders in Persian Gulf veterans that are high in light of the earlier evacuation

figures. The Fort Devons Operation Desert Storm Reunion Survey was conducted within 5 days of return to the United States before soldiers rejoined their families. The most commonly endorsed war zone stressors were formal alert for chemical or biological attack (approximately 75%), receiving incoming fire from large arms (approximately 73%), and witnessing death or disfigurement of enemy troops (approximately 48%). Four percent of 2136 men and 9% of 208 females met a presumptive diagnosis of PTSD. Symptoms of hyperarousal and exaggerated startle were the most commonly endorsed PTSD symptoms. Twenty-eight to 31% had general severity index (GSI) scores on the brief symptom inventory (BSI), which reflects general psychological stress, in the clinically significant range.

Approximately 6 months after Operation Desert Storm, Labatte and Snow administered a self-report questionnaire to 57 soldiers stationed in Germany who were members of a single mechanized infantry unit that suffered four casualties during the brief ground war. Fourteen soldiers (25%) reported traumatic nightmares within 2 months of the war. Nightmares began 2 to 6 months after the war for an additional nine soldiers (16%).

Two other studies assessed PTSD symptoms and general psychopathology in a large number of reservists within the first year of their return from the Persian Gulf. In a study of 591 Army, Navy, and Marine reservists, Perconte and co-workers found that those who had been deployed to the Gulf war combat zone had significantly higher Mississippi PTSD scores, higher Beck depression scores, and higher levels of global distress as measured by the symptom check list-90 (SCL-90) than reservists who had been activated but not deployed to combat zones. Over 15% of deployed reservists met Mississippi cutoff scores for PTSD compared to less than 4% of nondeployed reservists. Sutker and colleagues reported low levels of psychological distress in their overall group of 775 combat-deployed Reserve and National Guard troops. However, 12.5% of the sample were diagnosed with PTSD.

Approximately 1 year after the war, Holmes and colleagues evaluated 179 members of an Air National Guard unit who were never deployed to the Persian Gulf and compared them to 296 members of the same unit who were deployed. Most members of the deployed group did not experience any traditional combat stressors, although they were exposed to non-traditional combat stressors such as anticipation of missile attacks and biological warfare. Compared to the nondeployed, the deployed group had statistically higher mean scores on the Mississippi PTSD scale and on the GSI as well as on the obsessive-compulsive, depression, hostility, phobic anxiety, and paranoia

subscales of the BSI; 6.8% of deployed and 1.7% of nondeployed were identified as having increased risk for PTSD. The findings of this study suggest that multiple noncombat stressors were distressing enough to cause both PTSD and non-PTSD psychological symptoms in some deployed veterans.

In a follow-up study of the Fort Devons sample 18–24 months after the war, nearly half of the sample reported no physical or psychological symptoms. Twenty-seven percent believed that their psychological health had deteriorated since the war. PTSD symptomatology was significantly associated with high health symptom endorsement. Twenty-two percent of soldiers with high combat exposure met a presumptive diagnosis of PTSD compared to 8.1% with low combat exposure. Data were consistent with a number of recent studies suggesting that an apparent association between combat exposure and health is significantly mediated by a diagnosis of PTSD.

In a survey administered approximately 2 years after the war to 1524 deployed and 2727 nondeployed military personnel from Hawaii and Pennsylvania, Stretch and co-workers reported possible PTSD in 8.0% of active duty veterans and in 9.35% of reserve veterans who had been deployed to the Persian Gulf. By comparison, 1.3% of active duty nondeployed and 2.1% of reservist nondeployed met possible criteria for PTSD. The sample was also compared to a large group of deployed active duty Army veterans from the XVIIIth and VIIth Corps. The possible risk for PTSD in these groups was 15.2 and 12.9%, respectively. The authors speculate that these units had higher rates of possible PTSD because their duty was more dangerous and because they were evaluated 1 year earlier. Deployed personnel also scored significantly higher on the somatization, obsessive-compulsive, and hostility subscales of the BSI and the GSI.

As part of a follow along study of Gulf veterans from two National Guard units, Southwick and colleagues reported a rate of presumptive PTSD in 8.3% of 84 subjects 6 months after the war and in 10% of 64 subjects 2 years after the war. The greatest increase in overall PTSD symptoms occurred between 1 month and 6 months after the war, and symptoms of hyperarousal were elevated above re-experiencing and avoidance symptoms at 1-month, 6-month, and 2-year evaluations. Morgan and colleagues found evidence for anniversary reactions in this same group of veterans.

Approximately 5 years after the war, the Iowa Persian Gulf study group conducted telephone interviews with 1896 Gulf war veterans and 1799 personnel who served in the military during the war but who were not stationed in the Persian Gulf. Persian Gulf war personnel reported higher rates of PTSD (1.9%

vs. 0.8%), depression (17.0% vs. 10.9%), cognitive dysfunction (18.7% vs. 7.6%), asthma (7.2% vs. 4.1%), fibromyalgia (19.2% vs. 9.6%), alcohol abuse (17.4% vs. 12.6%), chronic fatigue (1.3% vs. 0.3%), and sexual dysfunction compared to non-Persian Gulf war military personnel. Symptom levels were generally higher in Persian Gulf war National Guard reserve personnel than in Persian Gulf war regular military personnel.

Finally, in a report of 18 495 Gulf war veterans who presented for evaluation to the Department of Defense Comprehensive Clinical Evaluation Program, 36% met ICD-9-CM diagnoses for psychological conditions. In most cases, symptoms did not develop until after the war. There was no apparent association between individual physical or psychological symptoms and specific exposures. Compared with a referent group of patients having no symptoms, an excess prevalence of disorders was highest for psychological conditions compared to a variety of physical conditions such as digestive and skin conditions.

Psychological Symptoms in Civilians Affected by the Persian Gulf War

Clearly the Gulf war had profound stress-related effects on Iraqi military personnel and civilians living in Iraq and surrounding Middle Eastern countries. In general, the rates of death, physical injury, and psychological injury have not been reported accurately in the scientific literature. However, there have been a number of publications related to the effects of the Gulf war on American and Israeli civilians as well as Vietnam veterans and Holocaust survivors.

In American civilians, it has been reported that the Gulf war was associated with mild to moderate symptoms of anxiety and depression, particularly in those who had a relationship with a deployed soldier. In children of deployed American soldiers, a major predictor of psychological symptoms was level of symptoms in other household members. Although deployment rarely provoked pathological levels of symptoms in healthy children, it was associated with increases in symptoms of depression, especially among younger children. In a study of Israeli civilians that was conducted during the war, Solomon and co-workers found that 80% of individuals whose homes had been destroyed by Iraqi missiles described symptoms consistent with DSM-III-R criteria for PTSD. Similarly, Laor and colleagues reported elevated levels of Gulf war stress-related symptoms in children and mothers who were displaced from their homes due to damage from SCUD missiles and in young children living in families characterized by inadequate cohesion.

In Vietnam veterans, no consistent response to the Gulf war has been described. Reported responses have included support for the war, anger at the U.S.

government for starting another war, irritability, intrusive thoughts, and increased depression and suicidality. In a study of 76 female Vietnam veterans with PTSD, Wolfe and colleagues reported some exacerbation of symptoms in most subjects, with the greatest increases in those who had high levels of preexisting PTSD symptoms. In a study of Holocaust survivors living in Israel during the Gulf war, Robinson and colleagues reported that many were still vulnerable 50 years after WWII and reported a revival of feelings and memories associated with the Holocaust.

Predictors of Posttraumatic Stress Disorder

Numerous investigations of WWII, Korean, and Vietnam veterans have shown that not all individuals develop PTSD and/or other psychological disorders after life-threatening traumas. Given an equal degree of traumatic exposure, some individuals are more likely than others to develop subsequent trauma-related psychopathology. In order to explain such individual differences in veterans of the Gulf war, researchers have studied a number of potential risk factors or predictors for the development of PTSD. These have included characteristics of the traumatic event, as well as available personal and environmental resources.

The most commonly cited risk factor for the development of PTSD is the nature and severity of the trauma itself. Many war-related investigations, including a number of Desert Storm studies, have demonstrated a clear dose-response relationship between the severity of psychological trauma and subsequent psychopathology (i.e., the more severe the trauma, the greater the likelihood of developing PTSD and/or other mental disorders). When traumatic exposure involves actual physical injury, the risk for subsequent psychopathology is even greater. In a hospital chart review study of medical and surgical patients who were evacuated from the Gulf to the Walter Reed Hospital, Brandt and co-workers reported a significantly higher rate of axis I disorders (and psychiatric symptoms of concern) in the hospital records of soldiers with traumatic injuries (e.g., shrapnel, gunshot wounds, motor vehicle accidents, SCUD missile attack) compared to soldiers without traumatic injuries (e.g., gastrointestinal bleeding, chest pain, malignancies). Other trauma-related risk factors identified in Gulf war veterans include exposure to dead or dying bodies, having a buddy wounded or killed in action, exposure to American soldiers killed or wounded by friendly fire, being in the reserve (e.g., lack of psychological preparation for deployment), and handling of human remains.

Personal variables that have been studied in Gulf war veterans include gender, race, intelligence, personality, hardiness, coping style, and perceived social

and family support. In a study of 653 Persian Gulf war zone-exposed veterans, Sutker and co-workers reported significantly greater psychological distress and PTSD symptoms in minority men compared to white men but no differences between war zone males and females. In a separate report, Sutker and colleagues found more avoidance, wishful thinking, and self-blame coping strategies; fewer problem-oriented coping strategies; lower scores on hardiness dimensions of commitment, control, and challenge; and less perceived social and family support among Gulf war veterans with PTSD ($n = 97$) compared to those without psychopathology ($n = 484$). No differences in intellectual sophistication as measured by the Shipley Institute of Living Scale were found between the two groups.

Physical Symptoms in Gulf War Veterans

Since the end of the Gulf war, a large number of veterans have reported an array of troubling physical symptoms, including fatigue, joint pain, gastrointestinal problems, skin rash, headache, memory loss, insomnia, and shortness of breath. In a relatively small percentage of veterans, specific etiologies for physical complaints have been linked directly to military service in the Gulf (e.g., leishmaniasis, malaria, and embedded fragments of uranium). However, for the majority of veterans with physical complaints, a specific relationship between physical symptoms and biological, chemical, or other environmental exposures has not been reported in the literature. Further, no specific medical diagnoses appear to explain most of the complaints. As a result, some have postulated a Gulf war syndrome to account for these unexplained physical symptoms.

While some studies clearly report a greater number of physical complaints among military personnel who served in the Gulf compared to those who did not serve in the Gulf, most have not found high rates of any one medical disorder or conclusive evidence for a new syndrome. To date, a number of expert panels (Defense Science Board Task Force, National Institutes of Health Technology, Institute of Medicine, Presidential Advisory Committee on Gulf War Veteran's Illnesses) have failed to identify a new Gulf war syndrome. For example, in 1996 the Institute of Medicine reported that "the committee has not identified scientific evidence to date demonstrating adverse health consequences linked with PGW service other than the documented incidents of leishmaniasis, combat-related or injury-related mortality or morbidity, and increased risk of psychiatric sequelae of deployment." Similarly, in 1996 Gray and associates reported no increased risk of prewar or postwar

hospitalization for any cause among 547 076 Persian Gulf war veterans compared to 618 335 nondeployed. Persian Gulf war veterans did have higher rates of psychiatric hospitalization that appeared to be related to the use of drugs and alcohol. Two large-scale mortality studies have reported no increased mortality as a result of medical diseases in Persian Gulf war veterans. However, an excess number of deaths due to accidents and unintentional injury have been reported.

Relationship between Physical and Psychological Complaints

In a comprehensive literature review on the relationship among psychological trauma, posttraumatic stress disorder, and physical health in diverse trauma populations, Friedman and Schnurr reported that exposure to catastrophic events (independent of actual physical injury) was frequently associated with adverse health reports and increased medical utilization, morbidity, and mortality. Based on work by Wolfe and others, Friedman and Schnurr's review suggested that PTSD – the reaction to a trauma – may serve as an important mediator in the association between traumatic exposure and perceived physical health. Baker and co-workers found support for this hypothesis in a sample of 188 Desert Storm veterans where fatigue, nausea, muscle aches, dizziness, back pain, stomach ache, and numbness were much more likely to be reported by Persian Gulf war veterans with PTSD compared to those without PTSD. Similarly, Stretch and colleagues reported a probable link between Gulf war syndrome and PTSD, even though they found the relationship between stress and physical health to be relatively weak in a large group of Desert Storm veterans. Approximately 30% of veterans with Gulf war syndrome also met criteria for PTSD. In a study of female veterans conducted within 1 year of their return from the Gulf, Wolfe and colleagues found anxiety and PTSD, but not combat exposure, to be significant predictors of health symptoms.

Neurobiological, psychological, and behavioral hypotheses have been offered to explain the relationship between PTSD and physical health. As noted by Friedman and Schnurr, medical problems in trauma survivors may result from neurobiological alterations characteristic of PTSD, such as exaggerated cardiovascular reactivity, adrenergic dysregulation, disturbed sleep physiology, altered hypothalamic-pituitary-adrenal axis activity, and enhanced thyroid function. It is also possible that these neurobiological alterations increase susceptibility to immunologic disorders and infections. Psychological and behavioral factors that may contribute to health problems and that are commonly seen in survivors with PTSD include hostility,

depression, alcohol and drug use, smoking, poor social support, and avoidant and emotion-focused coping.

Summary

Soldiers serving in the Gulf war were exposed to a wide variety of potential health risks, including traumatic stress. Across multiple studies it appears that between 6 and 10% of Gulf war veterans developed PTSD as a result of their service in the Middle East. A host of other psychological and physical symptoms have been reported, and some researchers have proposed a Gulf war syndrome. In Gulf war veterans the precise relationship among stress, the neurobiological alterations that accompany stress, and toxic or infectious exposure currently is poorly understood and the subject of intense scientific investigation.

Transactional Model of Stress

Summary

Glossary

<i>Appraisal</i>	The part of the transactional model related to an individual's cognitively assessing the demands of the event and determining his or her resources for coping with those demands.
<i>Attributional style</i>	The way an individual explains the causes of bad events.
<i>Coping</i>	The part of the transactional model related to strategies for enduring and overcoming stress.
<i>Expectation</i>	The part of optimism related to the anticipation of positive outcomes.
<i>Internal/external style</i>	The degree to which people blame the cause of bad events on themselves or on things outside of their control.
<i>Neuroticism</i>	A personality characteristic associated with such characteristics as emotional instability, physiological hyperreactivity, and a lowered threshold for the experience of a variety of negative emotions, such as anxiety, anger, irritation, depression, and distress.
<i>Optimistic bias</i>	The part of optimism related to an individual's perception that he or she is at a lower risk for negative events than the average person.
<i>Optimistic explanatory style</i>	The combination of having external, unstable, and specific explanatory styles with respect to bad events.
<i>Primary appraisal</i>	The estimate that an individual makes about the degree to which a particular event is a threat to his or her personal goals.
<i>Secondary appraisal</i>	The estimate that an individual makes about the degree to which he or she has the personal resources to cope with the demands of some particular event.
<i>Self-disclosure</i>	A coping strategy related to the expression of thoughts and feelings about upsetting events.
<i>Self-efficacy</i>	The part of optimism related to an individual's belief in his or her ability to do the behaviors necessary to achieve some desired outcome.

Specific/global style

The degree to which people blame the cause of bad events on factors that are particular to a given situation or on factors that are much more general and applicable to a large number of life situations.

Stable/unstable style

The degree to which people blame the cause of bad events on factors that are long lasting and relatively permanent or on factors that are more temporary and changeable.

Stress

The subjective feeling that is produced by events that an individual perceives as overwhelming and beyond his or her control.

Stress exposure

The part of the transactional model related to being in situations that have a high probability for evoking stress in the average person.

Stressor

An event capable of eliciting stress.

Transactional model of stress

A model that suggests that stress occurs when (1) an individual is exposed to a challenging event, (2) the person appraises the demands of the event and appraises his or her own resources for adjusting to those demands, and (3) the person initiates a strategy for coping.

Stress is the subjective feeling that is produced by events that individuals perceive as overwhelming and beyond their control. Events that typically elicit stress are called stressors. Not all people respond to stressors in the same way, however. Two people may undergo the same event, say a painful loss such as losing their job. One person may be devastated and completely overwhelmed, whereas the other may accept the event as a challenge and mobilize to take positive action. Differences between people in how they react to the same objective event highlight the fact that stress is not out there in the environment. Instead, stress really lies in the transaction between the individual and the characteristics of the environment. Personality processes may moderate this transaction; whether a particular event is experienced as stressful is determined, in part, by the personality characteristics of the person exposed to the event. This article reviews briefly the transactional model of stress and what is known about several stress-moderating personality processes.

Transactional Model of Stress

In general terms, the transactional model of stress, first formulated by psychologist Richard Lazarus,

holds that stress unfolds as follows: (1) an individual is exposed to a challenging event, (2) the person appraises the demands of the event (primary appraisal) and appraises his or her own resources for coping with those demands (secondary appraisal), and (3) the person initiates a strategy for coping. Outcomes then follow, such as a change in the situation or in the health, mood, or behavior of the individual. Personality processes can affect each of the three steps in this transactional model.

Stress Exposure and Neuroticism

Some personality variables are related to higher exposure levels to stress-initiating events. Many studies have documented the role of neuroticism in the exposure to events that elicit stress. Neuroticism is a broad and inclusive personality characteristic associated with such characteristics as emotional instability, physiological hyperreactivity, and a lowered threshold for the experience of a variety of negative emotions, such as anxiety, anger, irritation, depression, and distress. Individuals high in neuroticism (high-N) are frequently found to report greater rates of unpleasant events in their daily lives than low-N subjects, particularly social events such as family difficulties, problems with co-workers, and personal relationships that create conflict and distress. In general, high-N subjects report much more interpersonal stress in their lives than low-N individuals.

The process whereby high-N people come to be exposed to more stressful events is less well understood. One hypothesis is that high-N subjects evoke unfavorable reactions in others. That is, the general characteristics associated with neuroticism lead those around high-N people to react in ways that create stress for them. A second hypothesis is that high-N subjects simply elect to be in situations with higher conflict potential, seeking out those stress-provoking situations that are avoided successfully by low-N subjects. A third hypothesis is that high-N subjects have a lower threshold for reacting to potential stressors; that is, given the same event, high-N subjects exhibit a larger stress response than low-N subjects. Although a dozen or more studies report positive correlations between N and stress responses, more recent controlled laboratory studies using standardized stressors have found that high-N subjects react to identical stressors (e.g., an unpleasant mood induction) with more negative emotions than low-N subjects. For example, studies have shown that high-N people have more cortisol (a biological by-product of stress) in their systems following standardized stress tests than do low-N people. High-N subjects appear to react to challenging events in a way that amplifies their biological stress response. Other studies have docu-

mented that high-N subjects are more reactive to naturally occurring interpersonal and noninterpersonal events (e.g., financial stressors). Stress reactivity blends into the next step in the transactional model – how people cognitively process or appraise events can determine their degree of reactivity to that event.

Appraisal, Attributional Style, and Optimism

According to the transactional model of stress, in order for stress to be evoked for individuals, two cognitive events have to occur. In the first cognitive event, called primary appraisal, people perceive that the event is a threat to their personal goals; in the second necessary cognitive event, called secondary appraisal, people conclude that they do not have the resources to cope with the demands of the event. If either of these appraisals is absent – if people do not perceive the event as threatening or if they feel they have plenty of resources for coping with the threat – then stress is not evoked. If some event is perceived as being threatening to individuals' goals, yet people feels they have the resources necessary to meet that event, then they may experience the event more as a challenge than as stress. Alternatively, individuals may feel that they do not have the resources demanded by the event (secondary appraisal) and that the event is not important to their long-term goals (primary appraisal) and so may not respond with stress.

The appraisal step in the transitional model of stress highlights the importance of cognition in understanding how an event becomes stressful. Individuals may differ in how they cognitively process events such that some individuals experience more stress than others. Attributional style refers to individual differences in the way people explain the causes of bad events. For example, I might ask you why you just had a minor automobile accident. You might attribute your accident to your lack of driving ability, which is an internal attribution, due to you. Or you might attribute your accident to the car's being particularly difficult to drive because it is so unresponsive, which is an external attribution, due to something outside of your control.

Although people might explain any specific event with either internal or external attributions, most people tend to consistently lean in one direction or the other. That is, some people typically give internal explanations and others typically give external explanations. One way to think about attributional style is in terms of the question: Where does the person typically place the blame when things go wrong? For example, some people tend to blame themselves when something goes wrong (e.g., I crashed the car

because I am a clumsy driver) and others never blame themselves for any bad event (e.g., I crashed the car because the road was not built correctly).

In addition to the internal versus external style distinction, attributions can also be characterized as referring to stable versus unstable causes and to whether those causes are specific versus global. For example, say that you are asked why you got a low grade on an exam. An internal and stable attribution might be that you did poorly because you have low ability or are low in intelligence. This is a stable attribution cause because intelligence is thought of as a stable characteristic, as difficult to change. An internal but unstable attribution might be that you did poorly because you were tired that day. Being tired is an unstable attribution because you can get over that relatively easily. Global versus specific causes are whether the cause of the event is due to some global state of affairs or is specific. For example, in explaining a low grade in your statistics course, a global explanation may be that you are low in general intelligence; a more specific explanation may be that you just have trouble with numbers.

The three attributional style dimensions tend to be correlated in a particular pattern. Consequently, many psychologists prefer to view this pattern as a single personality dimension, which they call the optimistic versus pessimistic explanatory style. Optimists believe that they are in charge, that they are the master of their fates, and that their actions actually influence their outcomes in life. Pessimists, however, believe that they are fairly helpless when it comes to bad events and that nothing they can do will make much of a difference in preventing bad events. Consequently, optimists have the expectation that what they do will influence what happens to them, whereas pessimists expect that their behavior is not related to the outcome.

In addition to being related to an internal, unstable, and specific explanatory style, optimism is also related to other personality concepts. For example, optimism also includes the people's expectations that good events will be plentiful, and bad events rare, in the future; for example, optimistic people expect that they will achieve success in most areas of life.

Another related psychological concept, developed by psychologist Albert Bandura, is self-efficacy. This is the people's belief that they can do whatever is necessary to achieve some desired outcome. Self-efficacy also refers to the confidence people have in their ability to perform the actions needed to achieve some specific outcome. For example, if you lose the job you have had for many years, self-efficacy is your subjective belief and confidence that you can find a new job.

A third concept related to optimism concerns perceptions of risk. For example, imagine you are asked to estimate the probability of various unpleasant events happening to you using a scale from 0 to 100, where 0 means "it will never happen to me" and 100 means "it is certain to happen to me." The events you are asked to estimate include dying in a plane crash, being diagnosed with cancer, having a heart attack, and being hit by lightning. Optimists perceive that they are at lower risk for such negative events than the average person is. This is referred to as the optimistic bias, and it may actually lead people in general to ignore or minimize the risks inherent in life or to perceive the world as a fairly benign place.

Psychologists have theorized about the possible mechanisms whereby the optimistic explanatory style buffers stress. These mechanisms should not be viewed as competing hypotheses; instead, two or more of these mechanisms may be operating to buffer stress for optimists.

- **Immune system.** Researchers have shown that the immune systems of optimists respond to challenges better and with more strength than the immune systems of pessimists. Other researchers have examined how optimism relates to the progression of HIV. Although results are mixed, there are suggestions in the literature that optimists have a longer survival time after the development of AIDS symptoms, and that this may be due to stronger immune function among optimists.

- **Emotional mechanism.** There is a very large literature showing that optimists are resistant to depression. It could be that optimism is related to stress buffering indirectly because it protects people from depression and the debilitating consequences of this emotional condition.

- **Cognitive process.** Optimism may be related to an extensive set of beliefs that people have about themselves and the world, and these beliefs may, in part, promote a more positive or adaptive perspective toward potential stressors. For example, researchers have shown that optimism is related to the belief that people can maintain and promote their own positive life circumstances as well as the belief that they can reduce various risks. Other studies have shown that optimists see the world as less filled with hassles and therefore feel less stress than pessimists.

- **Social contact.** Pessimists tend to be loners, and social isolation is a reliable predictor of general distress and dissatisfaction with life. Friends and family may provide the earliest medical feedback when things start going bad. For example, a friend might say, "You look stressed today," or a roommate might remark, "You are looking really tired these days; is

something wrong?" Because pessimists are isolated and avoid social contact, they may have less of this social feedback and hence not have this source of information about their health status.

- **Direct behavior.** Optimism may set in motion certain behaviors that lead directly to benefits for coping. The answer to how optimism and coping are linked may be as simple as that optimists act differently and take better care of themselves and their circumstances than pessimists do. Behavior may prove to be the most critical link in the connection between optimism and coping, simply because optimists do more of the right things (e.g., exercising, sleeping enough, and getting advice from others) and fewer of the wrong things (e.g., drinking and distracting themselves from problems).

As a caveat, most of the research on the association of optimism and stress is correlational, and therefore psychologists cannot pinpoint exactly which factors are responsible for the correlations; they can only speculate. Future research will help determine what are the most effective components of the optimistic personality style in producing better health and a longer life.

Coping and Self-Disclosure

What are some of the strategies that people use to overcome stress and the accompanying feelings of anxiety, being overwhelmed, and being afraid? One strategy studied by psychologists is self-disclosure, the tendency for people to express their thoughts and feelings to others.

Many theorists have suggested that keeping things to ourselves (not opening up to other people) may be a source of stress and ultimately may lead to psychological distress and physical disease. These theorists have further argued that being open with others about our feelings may promote coping. For example, talk therapy may work, in part, because through it patients uncover secrets and reveal what they have been keeping to themselves.

Psychologist James Pennebaker is a leader in the field of self-disclosure. In some early studies, he asked subjects to think of something upsetting or traumatic that had happened to them, something they had not discussed with anyone. He asked his subjects to write these secrets down. People wrote about embarrassing moments, sexual indiscretions, illegal or immoral behaviors, humiliations, and so on. It is interesting that all subjects came up fairly quickly with a secret that they had been keeping.

Not discussing some upsetting event can lead to problems because it takes physical energy to inhibit the thoughts and feelings associated with such events.

It is not easy to keep a secret, and keeping something in, especially if it is a major trauma or an especially significant or upsetting event, takes a lot of energy. Over time the cost of keeping the secret builds and builds and can increase the likelihood of stress-related problems such as trouble sleeping, irritability, physical symptoms such as stomach aches and headaches, and even illness.

According to Pennebaker's early theorizing, telling the secret relieves the compounded stress of keeping it in. In other words, getting something off your chest is a relief from the cost of keeping it inside. Confronting the traumatic memory by telling someone or even writing about it releases the person from the work of keeping a secret. Letting the secret out by talking or writing about it lowers stress and improves the chances for coping and positive adjustment.

In his recent writings, Pennebaker has proposed a different mechanism of action for self-disclosure. By telling the story of some stressful event, people reinterpret the event, often finding a new way to think about it that lessens its impact. For example, a college student talking about a painful breakup may reinterpret the event to actually have some positive consequences (e.g., He really was not my type anyway). Telling others about misfortunes gives people an opportunity to reframe the event and to look for the silver lining in even the worst events.

Many researchers have conducted studies on the self-disclosure of stressful events or telling secrets. In some of these studies, researchers contacted subjects who had undergone a severe event, such as the loss of a spouse through accident or suicide. Subjects were asked how much they had discussed the event with friends, family, or other helping professionals, such as a priest or minister or therapist. Researchers also typically assessed the subjects' health during the time following the stressful event. Results typically showed that the more people had talked about the tragedy, the better their subsequent health. In other words, those who kept the trauma to themselves tended to suffer more problems subsequent to the event than those who disclosed their feelings to others.

In related research, experiments were conducted in which subjects were randomly assigned to conditions. In one condition, subjects were typically asked to recall and write about a distressing event. In the other condition, subjects were typically asked to write about some trivial topic, such as what they normally eat for breakfast. Results frequently showed that subjects writing about the traumatic event reported feeling more distress and discomfort while writing. However, follow-up surveys showed that subjects who wrote about a trauma typically had fewer illnesses compared to subjects who wrote

about trivial topics. Moreover, objective records (e.g., number of health-service visits) also suggest that subjects who self-disclosed about trauma did indeed have fewer illnesses than the subjects who wrote about trivial topics.

Other studies show that people who keep unpleasant information about themselves secret are more likely to develop anxiety or depression than those who tell someone. Often psychotherapists will ask their clients, especially those who have experienced a trauma or some extreme event, to talk or write about that trauma. Some psychologists even recommend that their patients keep a diary of the events in their life and how they are reacting to those events. Such a daily self-disclosure or private secret-telling helps people put their feelings into perspective and make some meaning out of the events in their life.

In summary, research on self-disclosure suggests that keeping traumatic events and the feelings about those events unexpressed can be stressful. Expressing emotions in words can, it appears, produce stress-reducing effects. Moreover, it appears that it does not matter how the feelings are put into words; it may not matter whether we talk to a trusted friend or relative, go to a caring psychotherapist, confess at our church, talk with our minister or rabbi, have a discussion with our husband or wife, or write it in a diary. Whatever form it takes, self-disclosure appears to be a personality process that can help people cope with stress.

Summary

The differences among people in how they respond to events exist because stress is not out there in the environment; instead, stress is in the subjective reaction of individuals to events. This is worth emphasizing because many people often refer to certain events as stressful, as if stress were an inherent characteristic of certain events. Instead, stress lies in how individuals respond to events.

Personality processes may have their effects at one or more points in the stress response. This article presents the transactional model of the stress response, which emphasizes three steps: exposure, appraisal, and coping. Certain personality characteristics have been associated with each of these steps; for example,

exposure has been associated with neuroticism, appraisal with attributional style and optimism, and coping with individual differences in self-disclosure. In reality, the steps of the stress response blend into one another, and so the personality processes presented here certainly overlap; for example, neuroticism may not only be associated with stress exposure, but may also be associated with coping efficacy. In addition, because of space constraints, there are other personality processes in the literature that were not discussed, such as the personality variables hardiness, locus of control, and emotional intelligence. Moreover, there are many individual differences related to health behavior (e.g., smoking, exercise, and social support) that may provide buffers for stress. Identifying and understanding individual differences in the stress response are fascinating and important goals for psychological research.

stressor); usually, but not invariably, has the connotation that the environmental event is detrimental or experienced as negative or unpleasant.

Stress

General Clinical Psychopharmacology

Psychopharmacology of Stress

Conclusion

Glossary

<i>Acute stress disorder (ASD)</i>	The disordered human stress response that occurs in the first month after exposure to a trauma (stressor).
<i>Fight or flight</i>	Types of reactions in which organisms engage as adaptive responses to environmental demands.
<i>General adaptation syndrome (GAS)</i>	A name given to the organism's reaction to a stressor as described by Hans Selye. The GAS is comprised of three main features – thymic and lymphatic involution, gastric ulceration, adrenal hypertrophy.
<i>Homeostasis</i>	The hypothetical idealized state of the body (<i>milieu interieur</i>) in which all physiological functions are in their optimal basal or most unperturbed conditions.
<i>Neuro-transmitter</i>	Any chemical in the brain or other part of the nervous system that carries information among nerve cells.
<i>Posttraumatic stress disorder (PTSD)</i>	The disordered human stress response that occurs subsequent to the first month after exposure to a trauma (stressor).
<i>Psychopharmacology</i>	The study of the pharmacological mechanisms of, or the therapeutic use of, drugs that affect the functions of the nervous system related to behavior and complex brain functions.
<i>Stress</i>	The complex of biological, psychological, and behavioral changes (that is, the stress response) that occurs as an attempt by an organism to respond adaptively (not necessarily successfully) to exposure to an environmental event (that is, the

Stress

Stress is a widely used hypothetical concept that refers both to environmental events that evoke organismic responses and to the responses themselves. There is little systematic data on either the efficacy or appropriateness of using drugs to prevent or modify the normal stress response. In contrast, a persistent disorder of the stress response (posttraumatic stress disorder [PTSD]) can be at least partially relieved by medication. The most efficacious drugs are the antidepressants, especially the selective serotonin reuptake inhibitors (SSRIs). Furthermore, there are medications that can both relieve the acute stress response and diminish the likelihood of developing PTSD (benzodiazepines and β -adrenergic blockers).

The Definition of Stress

Before reviewing information concerning the psychopharmacological treatment of stress, it is essential to attempt to define stress. This is difficult, and not all individuals involved in stress research or the treatment of people with stress disorders are likely to agree with any particular definition. It is important, nonetheless, to identify basic issues about the definition of this concept as it has been used over the past half century.

Stress has generally been defined in one of two fundamental ways. In the first, stress is an environmental event or circumstance that produces an effect of a particular kind on the organism. That effect has been called the stress response (see **Evolutionary Origins and Functions of the Stress Response, Genetic Polymorphisms in Stress Response, Seasonal Changes in Stress Responses, Sex Differences in Human Stress Response**).

Alternatively, stress has been used to refer to the effects that occur in the organism. In this case, the

environmental event is typically called the stressor. Whenever stress is discussed, one must know in which way the speaker or writer is using the term. For the psychopharmacological treatment of stress, the word is typically used in the second sense, that is, to modify the effect of a stressor on the organism. If one wished to treat stress in the other sense, that would involve not changing the organism's response with treatment, but rather changing the environment itself. In other words, it would involve developing strategies to diminish the occurrence of stressors (a difficult thing to do in real life, and unlikely to involve drugs).

Circularity in the Definition of Stress

An ambiguity or circularity exists in the definitions of stress. In a situation in which an environmental event is quite different from normal circumstances (in other words, unambiguously traumatic), and especially if the event is not avoidable or escapable by the organism (assuming it is a negative event or circumstance, which is usually – but not always – considered to be the case in stress), most people would agree that a stress or stressor has occurred. These are the kinds of events often used in stress research, especially with animals. However, in more typical real-life circumstances, it is frequently not as clear whether a stressor has occurred. For example, while some people find sky diving exhilarating and enjoyable, others find it very frightening. Is it a stressor? Is it a stressor only for those who report a negative subjective response to it? Is it a stressor for anyone who reports a strong subjective reaction, positive or negative? Is it a stressor for everyone, but some people cope with it more effectively? How can stress be unambiguously defined and recognized?

In an attempt to avoid this dilemma, some have advocated using the organism's response instead of the environmental event as the defining characteristic. Classic markers have included physiological reactions such as changes in heart rate, blood pressure, and sudomotor response (sweating), as well as changes in hormones, especially glucocorticoids (such as cortisol) and epinephrine (adrenaline). In this situation, there is a risk that the physiological (or other) changes will be equated with stress rather than being a marker of it. Unless an external event or circumstance is so extraordinary that all observers agree to its divergence from normal circumstances, this definitional problem appears to be almost inevitable. The issue of normal versus abnormal stress is important in understanding the treatment of stress, as described next.

Stress Normal and Abnormal, and Homeostasis

In the middle of the nineteenth century Claude Bernard defined the concept of the *milieu interieur*, his point being that the organism regulates all of the physiological processes going on in the body (under the skin). Early in the twentieth century, Walter Cannon hypothesized that the organism seeks homeostasis, that is, there is an optimal status for the *milieu interieur*, and the organism attempts to maintain that set of conditions. While there is much truth to this concept, it has been found to be an oversimplification. For example, most physiological processes have been shown to fluctuate normally over predetermined time cycles, for example, the circadian (around 24 h) rhythm and the monthly menstrual cycle.

In the context of homeostasis, ignoring the definitional problem, stress can be understood as a perturbation of this set of psychological, physiological, biochemical, and even gene expression states. A fundamental question thus arises: is the stress response – the organism's response to the stressor – a normal reaction? And, if so, what is its function?

Cannon gave an answer to this question, although he was not thinking exactly in terms of the stress response. He viewed the various physiological changes that occur as preparing the organism for fight or flight, in other words, for action. Extensive study of the multitude of reactions that occur during the response to the stressor has generally been consistent with this hypothesis. In short, Cannon was largely correct.

Perhaps the scientist most closely associated with the concept of stress was Hans Selye. He called it the general adaptation syndrome (GAS). He viewed the stress response somewhat differently, not clearly as an adaptive mechanism but as evidence of dysfunction, at least in its more extreme form. In short (admittedly an oversimplification), both Cannon and Selye viewed the changes that are now called the stress response as normative, that is, always or almost always occurring when a stressor is present. However, Cannon viewed the response as adaptive and healthy, while Selye viewed it, at least in its more severe form, as destructive.

Disorders of Stress

Whether or not one views the stress response as adaptive, it does appear that it is normal; in other words, it does always or almost always occur when a stressor is present, at least if the stressor is intense enough. It is also true, however, that a minority of individuals experience stress responses that are abnormal in character, intensity, and/or duration.

Clinical descriptions of detrimental psychological changes occurring in response to traumatic events go back at least as far as the Civil War, and probably much earlier. Phenomena previously identified by such terms as soldier's heart and shell shock refer to such changes occurring in association with traumatic events in war, but these negative psychological reactions can occur to a wide variety of severely traumatic events. The current psychiatric diagnosis nomenclature, as sanctioned by the American Psychiatric Association, is called the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition (DSM-IV). In it, these detrimental changes are defined as disorders, and are classified as anxiety disorders. The two specifically defined disorders are acute stress disorder (ASD) and PTSD. The diagnostic criteria for these two disorders are listed in Table 1.

The major differences between the two types of stress disorders are (1) the duration criterion, (2) the dissociation criterion, which is present only in ASD, and (3) the exclusion criterion for substance use, etc., which also is only in ASD. However, for the purpose of this article, the main issue is the fact that both stress disorders are just that, disorders. In other words, these are not descriptions of how the normal or modal person responds to a traumatic event. These are descriptions of how responses occur when they go wrong in some way, definitions of abnormal responses. Research has shown that the majority of people who experience most kinds of traumatic events do not develop stress disorders. Predictors of who will develop these syndromes after experiencing

a trauma are beginning to be identified. Treatment is usually recommended only for the individuals who develop a stress disorder; the question of whether or not (and under what circumstances) to treat the stress response – that is, to treat any individual exposed to a severe stressor – is revisited at the end of this article.

General Clinical Psychopharmacology

Before discussing the treatment of stress disorders with psychopharmacological agents, a brief introduction to psychotropic drugs is in order. Major classes of these drugs are listed in Table 2. The two classes that are most useful in the treatment of PTSD – antidepressants and anti-anxiety drugs – are listed separately. The remaining drugs are listed only as the major classes rather than the individual drug groups.

In many branches of medicine, drugs are listed in classes related to the first or most well defined use for which they have been shown to be effective. For example, a number of drugs with various chemical structures – heterocyclics, monoamine oxidase inhibitors (MAOIs), SSRIs – are all called antidepressants because (1) they all demonstrate an antidepressant effect, (2) this is a very important effect, and (3) this is often the effect for which each drug was first demonstrated to have benefit. Despite this, drugs in the group of antidepressants are beneficial for a variety of disorders. For example, the heterocyclics are also used to treat enuresis (bed wetting), some kinds of pain, obsessive-compulsive disorder, and panic anxiety disorder. MAOIs are useful, for example, for panic disorder and social phobia. SSRIs treat a wide

Table 1 DSM-IV diagnostic criteria for acute stress disorder (ASD) and posttraumatic stress disorder (PTSD)

Acute Stress Disorder (ASD)

- A. Exposure to a traumatic event
- B. Three or more of five dissociative symptoms
- C. Persistent re-experiencing of the event
- D. Marked avoidance of stimuli that arouse recollections
- E. Marked symptoms of anxiety or arousal
- F. Clinically significant distress or impairment
- G. Occurs within 4 weeks of the event and lasts between 2 and 28 days
- H. Not due to a substance, medical condition, or other psychiatric disorder

Posttraumatic Stress Disorder (PTSD)

- A. Exposure to a traumatic event
- B. Persistent re-experiencing of the event in one or more of five ways
- C. Persistent avoidance and/or numbing in three or more of seven ways
- D. Persistent increased arousal in two or more of five ways
- E. Duration is more than 1 month
- F. Clinically significant distress or impairment

6. Cognition enhancers
7. Narcotic analgesics
8. Drugs for substance abuse prevention

variety of disorders such as panic disorder and the eating disorder bulimia nervosa. The antidepressant drugs, especially the SSRIs, are the drugs that have been demonstrated most clearly to have benefit for people with stress disorders.

The other class of drugs for which there is controlled-trial research concerning treatment of the stress disorders is the benzodiazepines. These drugs are used most widely as anti-anxiety agents. They are also used as sedatives, muscles relaxants, hypnotics (sleeping pills), and anticonvulsants (anti-seizure). This class includes such drugs as alprazolam, diazepam, and clonazepam.

As can be seen in Table 2, there are several other groups of drugs classified as psychopharmacological agents. Either these other groups have not been tested for the treatment of stress disorders, or the studies have not been controlled trials. Table 2 does not contain all drugs or drug groups with psychotropic effects that are potentially useful, however; undoubtedly new drugs will be added in the future.

Psychopharmacology of Stress

In addressing the question of how to treat stress with medications (or otherwise), the first issue that arises is which meaning of stress is under consideration. In addition to PTSD and ASD, many psychiatric syndromes such as schizophrenia, depression, and various anxiety disorders, as well as various medical disorders, are often considered as involving stress. The concept of stress is used very broadly, while research specifically related to DSM-IV defined disorders of stress is much more restricted. Only a small number of controlled studies have been published.

Acute Stress Disorder (ASD)

There has been less research on the treatment of ASD than on that of PTSD, but two issues have emerged. First, medications with rapid onset of effect that can reduce anxiety and/or arousal-like symptoms appear to be appropriate sometimes. Second, a number of acute risk factors for development of PTSD have been identified, including the occurrence of acute stress symptoms and especially adrenergic arousal-like symptoms (mainly, elevated heart rate soon after the stressor, and also elevated urinary epinephrine). (History of childhood trauma, severity and persistence of physical injury, and abnormalities of cortisol secretion are among the other implicated predictors.) Specific medications potentially useful to treat acute stress symptoms include the benzodiazepines and the β -adrenergic blocking drugs (which also can reduce the likelihood of developing PTSD).

Posttraumatic Stress Disorder (PTSD)

Even though the relationship between the experience of a highly disruptive event and the development of post-event PTSD symptoms has been known for many years, systematic research into the use of psychopharmacological agents to treat this type of symptoms has been ongoing for only about 20 years. The number of studies is relatively small, and the number of controlled studies is smaller still. One reviewer has summarized these studies by concluding that drug treatment has modest but meaningful effects.

Specific drugs for PTSD Controlled studies of drug treatment of PTSD have mainly evaluated drugs in the antidepressant class. Among the heterocyclic antidepressants, there is evidence for benefit from imipramine, amitriptyline, and probably chlorimipramine. It appeared that approximately two-thirds of the treated individuals experienced meaningful improvement. The symptoms most likely to improve were intrusive symptoms such as distressing recollections or dreams. Avoidance symptoms were typically less responsive. On the other hand, desipramine did not appear to be as helpful. It has been observed that the drugs that were most helpful have a more prominent effect on the neurotransmitter serotonin in the brain, while less beneficial drugs have a more prominent effect on the brain neurotransmitter norepinephrine.

Antidepressants from two other groups, MAOIs and SSRIs, have also been analyzed in controlled studies. Results with MAOIs have been mixed, but have also supported their usefulness for intrusive symptoms. SSRI drugs have shown robust benefit, not only for the intrusive symptoms but also for avoidance and numbing. For all of these medications, early improvement was associated with a better ultimate outcome, but significant benefit nonetheless typically required 5–8 weeks or more, and further improvement was sometimes observed well beyond 8 weeks.

The benzodiazepine alprazolam was assessed in a controlled trial. It was less beneficial than the antidepressants. Hyperarousal symptoms did, however, show some improvement. Other benzodiazepines are also likely to show benefit for the hyperarousal symptoms.

In addition to the controlled studies, a number of uncontrolled treatment trials have been reported, and a number of different drugs and drug classes have been assessed. Although these results must be viewed as preliminary, promising drugs include the anticonvulsant mood stabilizers carbamazepine and valproic acid. Other drugs also probably have a role as second-tier agents to be used either in combination

with the first-tier drugs or when the first-tier drugs fail. These include the mood stabilizer lithium, the β -adrenergic antagonist drugs, the α_2 agonists, the nonbenzodiazepine anti-anxiety agent buspirone, the sedating antidepressant trazodone, and opiate antagonists (possibly beneficial for numbing symptoms). Antipsychotic drugs are not indicated for PTSD unless psychotic symptoms are present.

Issues and factors in drug treatment of PTSD The definition of PTSD includes three groupings of symptom types: (1) intrusive, (2) avoidance and numbing, and (3) hyperarousal. The heterocyclic antidepressant drugs (primarily those that predominantly affect serotonin) and the MAOIs have been shown to be most beneficial for the intrusive symptoms. SSRIs are also beneficial for the intrusive symptoms, as appears to be the mood stabilizer anticonvulsant carbamazepine. Considering all three types of symptoms, SSRIs appear to be the most beneficial. In general, the intrusive symptoms are probably the ones most responsive to drug treatment.

The avoidance and numbing symptoms appear to be the most difficult to control. They are least likely to improve, and they require the longest treatment – many weeks – before improvement occurs, if it occurs at all. The antidepressant drugs, mainly the SSRIs, are most likely to produce improvement for these symptoms.

Hyperarousal symptoms seem intermediate in their likelihood of response. Benzodiazepines, buspirone, and the β -adrenergic antagonists are most specifically efficacious for the hyperarousal symptoms.

Several other issues in the drug treatment of PTSD are noteworthy. Not only do these drugs take longer to provide benefit for PTSD than they usually do for depression (2 months or more versus approximately 1 month), but they often require higher doses. Often only partial symptom relief is attained with the drugs now available. A total treatment program, including nonpharmacological treatments, is almost always appropriate. The presence of comorbid disorders such as depression, other anxiety disorders, and personality disorders modulates treatment outcome, although the direction of effect is variable. For example, some research suggests that the presence of depression improves prognosis, while other research suggests prognosis is worse when depression is present, possibly because of the increased overall severity due to two co-existing (comorbid) disorders. (Medication benefit does not depend on the presence of a comorbid disorder.) The presence of a personality disorder, especially antisocial personality, makes prognosis worse. The source of the trauma (for example, combat

Table 3 Factors and goals of drug treatment of PTSD^a

1. Improve intrusive symptoms
2. Control avoidance and numbing symptoms
3. Reduce hyperarousal symptoms
4. Provide distance between the individual and intensity of the emotional experience
5. Relieve depressive symptoms
6. Minimize irritability and aggressiveness
7. Gain control of dissociative and psychotic symptoms if they occur
8. Facilitate efficacy of psychotherapy

^aModified from Vargas and Davidson (1993).

versus non-combat related) can influence outcome. Finally, it is likely that the earlier that treatment is provided after the PTSD syndrome develops (or even in the first month after the trauma – ASD), the more improvement can be anticipated.

It has been suggested that the phasic (intermittent) PTSD symptoms are more responsive to treatment than the tonic (persistent) symptoms. A list of the ways in which drug treatment can be helpful in the management of PTSD appears in [Table 3](#).

Stressful Circumstances: Should Normal Stress Be Treated?

The research reviewed previously demonstrates that medications are beneficial, but not usually curative, for PTSD. Older research had suggested the use of sedative drugs for abreaction for ASD, a treatment now not generally recommended. Some clinicians have suggested that sedation, possibly including sedative effects from benzodiazepines, might be detrimental, although the anti-arousal, anxiolytic effects can be acutely beneficial. These data lead to the question, can the normal stress response itself be diminished or prevented effectively (with pharmacological and/or other means)? Should it be?

If one views the stress response as Cannon conceived of it (that is, the fight-or-flight reaction), it would seem that prevention of this normal physiological and behavioral response to environmental stressors would be detrimental rather than beneficial. On the other hand, if one views the stress response as Selye did, that is, as a reaction that at least in its more severe form is harmful to the organism, preventing it would be appropriate. As pointed out by Yehuda and McFarlane, there is considerable confusion about the relationships among stressors, potential detrimental effects of the stress response itself, and the development of PTSD. For example, although it is widely believed that stress has many negative consequences on health, the relationship between stress and the development, maintenance, and/or

exacerbation of specific medical symptoms and syndromes remains at best only partially understood. Provocative preliminary hypotheses exist, such as the apparent detrimental effects of chronic elevations of corticosteroid stress hormone substances on specific areas of the brain (especially the hippocampus, a structure very important for normal memory function), but much more needs to be known to clarify these linkages. It seems that the answer to the question of whether to treat normal stress must await not only additional data, but also improved clarity concerning the definition(s) and use of the word and concept of stress as applied to humans in clinical situations. What is clear is that abnormal stress responses call for intervention.

While investigators and clinicians struggle to obtain greater conceptual clarity in the field of stress research and treatment, new data have begun to address the question of early pharmacological intervention for abnormal stress responses. Some early risk factors, predictive of increased likelihood of the development of PTSD, can now be used to lower that risk. Specifically, the presence of an elevated heart rate or other evidence of significant adrenergic activation soon after the trauma appears to call for measures, pharmacological and/or nonpharmacological, to promptly lessen this activation.

Conclusion

Disordered chronic responses to significant stressors (PTSD) are treatable with medications, although most people with the disorder do not experience a full remission from drug treatment, and some symptoms (avoidance and numbing) are harder to treat than others (intrusive, hyperarousal). Most individuals need a treatment program including pharmacological and nonpharmacological methods to derive maximal benefit. Prophylactic drug treatment given soon after trauma exposure to reduce arousal can diminish the risk of subsequent development of PTSD. The larger question of whether or not stress per se is treatable (that is, the normal stress response is diminished or prevented), and whether or not that would be advantageous or disadvantageous to the organism, depends in part on which definition of stress is under consideration.

Chemical Communication and Social Odors

The Vomeronasal Organ

Vomeronasal Organ Response to Olfactory Stimuli and
Olfactory System Response to Pheromonal Stimuli

Stress and Reproduction

Stress Signaling Mediated by Pheromones

Glossary

<i>Accessory olfactory bulb (AOB)</i>	A neural structure located at the dorso-caudal end of the main olfactory bulb but distinguished from the main olfactory bulb by the types of signals detected and by its central nervous system projection sites.
<i>c-Fos immunocytochemistry</i>	A method for measuring cellular activation by detecting the expression of the c-fos oncogene.
<i>Chemo-architecture</i>	The relationship between cellular topography and the cellular machinery used in signal detection and processing.
<i>Chemosensory stimulation</i>	An environmental stimulus detected by a sensory system via ligand–receptor binding.
<i>Gonadotropin-releasing hormone (GnRH)</i>	A decapeptide produced in the hypothalamus, responsible for stimulating the release of luteinizing hormone from the pituitary gland; also referred to as LHRH.
<i>Sociogenic stress</i>	A set of stresses caused by conspecific interactions.
<i>Vomeronasal organ (VNO)</i>	a specialized chemosensory structure for pheromone signaling.

Chemical Communication and Social Odors

Interorganism communication is an indispensable feature of species survival, and the signals employed for this purpose are quite diverse. Among the various senses employed, chemosensation (the detection and transduction of chemical environmental stimuli) is

perhaps the most primitive. In addition to aiding in locating nutrition, chemosensory transduction allows an animal to find suitable mating partners and avoid dangerous predators. Pheromones are compounds used for intraspecies chemical communication that are secreted or excreted by one individual and elicit behavioral or physiological responses in the recipient. However, the great diversity of signals used in chemical communication by vertebrates suggests that this communication is not mediated exclusively by pheromones. A multiplicity of signals may be present in the same secretion, and it is unlikely that the response to this complex signal is mediated exclusively by a single sensory system. Johnston has recently suggested the term chemical signals for the wide array of odors regulating vertebrate behavior and physiology. Indeed, various chemosensory structures have been found in vertebrates that transduce chemosensory cues. Pheromones act on the recipient through olfaction, ingestion, or absorption; however, all mammalian pheromones studied so far act through olfactory pathways. Olfactory-mediated pheromonal communication in mammals is used to organize a wide range of social behaviors, such as mating, dominance, aggression, and maternal bonding, and hence these cues are also frequently referred to as social odors.

Mammalian pheromones elicit both long-lasting effects that bring about changes in the endocrine state of the recipient animal and short-term rapid effects on the recipient's behavior. For example, male mouse pheromones have been shown to induce advanced onset puberty in female counterparts (the Vandenberg effect), the onset of estrus (the Whitten effect), and the termination of pregnancy (the Bruce effect) by an increase in luteinizing hormone (LH) and a decrease in prolactin. Female mouse pheromones cause a delay in the onset of puberty and a suppression of estrus in other female mice by increased release of prolactin. These delayed neuroendocrine effects on reproductive physiology and behavior have been termed the primer effect of mammalian pheromones.

The faster-acting releaser effects are elicited immediately, and these pheromones have been implicated in the regulation of intermale aggression, initiation of male ultrasonic vocalization and copulatory behavior, induction of lordosis (the receptive posture adopted by female rodents anticipating sexual intercourse), and parental care. Releaser effects are also

modulated by the hormonal status of the animal, which is itself under pheromonal regulation. Gonadotropin-releasing hormone (GnRH) and LH play crucial roles in regulating these pheromone-induced fast behavioral responses.

The Vomeronasal Organ

Pheromone molecules are chemically unrelated and are contained in body fluids such as urine, sweat, and sebum. Pheromones are detected by peripheral sensory neurons sequestered in a tiny cigar-shaped bony capsule called the vomeronasal organ (VNO) or Jacobson's organ (Figure 1a). Located bilaterally on the posterodorsal aspect of the nasal septum, this tubular structure opens into the nasal or oral cavity via the vomeronasal duct, allowing chemical stimuli to reach VNO neurons from both the nose and mouth. In some mammals such as ungulates and felines, the males display a behavior called flehmen, which consists of curling of the upper lip and throwing the head up after investigating the female's genital area. This helps in facilitating the transport of the odorous compounds in female urine into the VNO of male, thus allowing the detection of the female's receptive state. In rodents, however, a pumping activity of the VNO associated with the autonomic afferent system appears to actively draw pheromone compounds into the lumen of the VNO, where they bind to receptors. These receptors lie on microvillous extensions of the dendrites of the vomeronasal

receptor neurons (VNRNs). Patch clamp recordings from dissociated VNRNs reveal that they possess voltage-gated inward and outward currents consistent with the ability to generate action potentials. VNRNs from the mouse respond to putative pheromones from mouse urine with the generation of an outward current accompanied by a decrease in membrane conductance (Figure 2). In a current clamp mode, pheromone application causes hyperpolarization of the membrane. The binding of pheromone molecules to their specific membrane receptors activates an intracellular signaling cascade involving G-proteins ($G_{\alpha_{i2}}$ in the apical neurons, G_{α_o} in basal neurons), phospholipase C- β (PLC), and diacylglycerol (DAG). DAG, the second messenger, is the gating factor for a cation channel known as transient receptor potential channel 2 (TRPC2), whose opening leads to an influx of $\text{Na}^+/\text{Ca}^{2+}$ that causes membrane depolarization. The spread of membrane depolarization along the dendrite leads to the activation of voltage-gated Na^+ and K^+ channels, with the consequent generation of an action potential. The propagation of impulse along the nerve fibers allows VNO neurons to communicate with the first central processing unit, the accessory olfactory bulb (AOB).

Much insight into the molecular and anatomical components of VNO-signal transduction has been gained from the study of mutant mice. Mice that lack a functional TRPC2 channel show normal olfactory function but fail to respond to urinary vomeronasal stimuli. These mice do not display male-male

Figure 1 Rodent vomeronasal organ (VNO). a, Sagittal view showing the location in relation to the main olfactory epithelium; b, anatomy and central neural projections, with the sensory vomeronasal receptor neurons (VNRNs) shown in a coronal cross section of the VNO. Two discrete classes of VNRNs (V1Rs and V2Rs), G-protein-coupled receptors, project separately to the anterior and posterior accessory olfactory bulb (AOB), respectively. The V2Rs differ markedly from the V1Rs in that they have a large extracellular N-terminus and form a receptor complex with members of the M10 family of major histocompatibility complex (MHC) class Ib molecules and β_2 -microglobulin ($\beta_2\text{m}$). The information from the V1Rs and V2Rs are processed in the AOB and then converges in overlapping projections to the bed nucleus of the stria terminalis (BNST), bed nucleus of the accessory olfactory tract (BAOT), medial amygdala (MeA) and the posteromedial cortical nucleus (PMCo) of the amygdala. COOH, From Brennan, P. A. and Keverne, E. B. (2004), Something in the air?: new insights into mammalian pheromones, *Current Biology* 14, R81–R89, with permission.

Figure 2 Application of the putative pheromone dehydro-exo-brevicomin (DHB) to a VNRN evoked an outward current accompanied by a decrease in conductance. Depolarizing pulses of 10 mV were applied continuously before (1), during (2), and after (3) DHB or bath. In the presence of DHB, the amplitude of the current pulses was decreased. From Moss, R. L., Flynn, R. E., Shen, X. M., et al. (1997), Urine-derived compound evokes membrane responses in mouse vomeronasal receptor neurons, *Journal of Neurophysiology* **77**, 2856–2862, with permission.

aggression and engage in sexual and courtship behaviors toward both males and females. They also have deficits in maternal aggression toward male intruders. This lack of aggressiveness in these mutant mice is in accordance with similar findings in mice following VNO lesions. The mouse VNO has two broad receptor gene families, V1Rs and V2Rs, comprising over 250 receptors genes. When the genes for 16 of the V1R family clustered together were deleted using chromosomal engineering (which amounted to 12% of the V1R population), male mice were impaired in their sexual behavior toward females, with fewer males initiating sexual activity toward females than the genetically intact controls. These mice, too, fail to initiate maternal aggression toward intruder males, as was found in TrpC2-deficient mice, although there were no differences in the aggressive behavior of these V1R cluster-deficient males. These and other studies have yielded important insights into the functioning of the vomeronasal system and have helped researchers appreciate the complexities of this chemosensory system.

Chemoarchitecture of the Vomeronasal Organ to Accessory Olfactory Bulb Projection

The diversity in electrical responses of VN receptor neurons to putative pheromones, as well as the vast array of behaviors subjected to pheromone regulation, may be related to the fact that VNRNs appear to be divided into at least two chemoarchitecturally

distinct populations: VNRNs located in layers close to the lumen of the VNO express $G_{\alpha_{i2}}$ and project to the anterior portion of the AOB; VNRNs located more basally express G_{α_o} and project to the posterior part of the AOB. The significance of this division has become more apparent with studies identifying two families of VNO receptor genes, with V1Rs and V2Rs expressed in $G_{\alpha_{i2}}$ and G_{α_o} VNRNs, respectively. This expression pattern suggests that there exist two functionally distinct processing units responsible for relaying signals from the VNO to the AOB.

Until now, the physiological basis for chemoarchitecturally segregated populations of VNO neurons was largely unexplored. Presuming that both populations of VNO cells are involved in pheromone detection, they may recognize separate categories of pheromones (volatile vs. nonvolatile, or primer vs. releasing) or may be involved in the mediation of separate behavioral responses. In the male mouse, the VNO is involved in at least two distinct behaviors: reproduction and aggression. Experiments have demonstrated that neurons in the anterior portion of the AOB of the male mouse are preferentially activated by exposure to female-soiled bedding, as opposed to familiar male-soiled bedding. The differential activation was dependent on an intact VNO and was not observed in the main olfactory bulb (MOB). These data indicate that the position of a vomeronasal receptor cell within the VNO is reflected at the level of the AOB by a functional division along the anterior–posterior axis.

Recently, Katz's group performed the first recordings of pheromonal responses in the AOB of awake-behaving mice that demonstrated that responses of the AOB mitral cells are highly selective to strain and the sex of conspecifics. It is also possible that nuclei downstream of the AOB, such as the medial amygdala (mAMG), may also be preferentially activated. The nature of the information processing by V1Rs and V2Rs is yet to be understood, but the anterior and posterior AOB projections completely overlap at the level of amygdala, the bed nucleus of the accessory olfactory tract (nAOT), and the bed nucleus of the stria terminalis (BNST).

Central Neural Pathways of the Vomeronasal System

The anatomical pathway linking pheromone detection in the VNO to the hypothalamic centers controlling sexual and reproductive events has been well defined by studies using transsynaptic tracers. VNRNs project directly to the AOB, where they synapse onto mitral cell dendrites. The mitral cell axons project to the mAMYG, BNST, and nAOT. Connections between the mAMYG and the preoptic area (POA) and between the mAMYG and the ventromedial hypothalamus (VMH) complete the circuit by which pheromones may modulate the hypothalamic and/or limbic centers involved in reproductive behavior. Lesions of the VNO, AOB, mAMYG, or VMH significantly impair the ability of the female rat to display increases in sexual receptivity in response to male sexual contacts. The possibility of direct projections from the VNO to the POA and VMH has received some support and may provide an additional pathway for pheromonal control over GnRH-secreting neurons located in the hypothalamus. The surgical removal of the VNO adversely affects the copulatory behavior in males and lordosis behavior in female rodents. GnRH has been shown to facilitate mating behavior in the female rat, and GnRH has also been demonstrated to restore mating behavior in the female rat and male hamster after VNO removal.

Activation of Vomeronasal Neural Pathways

Studies employing c-fos-immunocytochemistry as a marker of cellular activation have revealed that vomeronasal neurons are activated by chemosensory stimulation. Following mating with a male, female rats exhibited a VNO-dependent increase in c-fos expression in all vomeronasal system nuclei. A particularly dense concentration of activated cells was observed in the mitral and granule layers of the AOB (Figure 3a) and in the mAMYG (Figure 3b), with increases in cellular activation also noted in the

Figure 3 Samples from female rats exposed to 3 h of repetitive mating. a, the accessory olfactory bulb; b, the medial amygdala (mAMYG). c-Fos-immunopositive cells are indicated by small black dots. Note the cluster of c-fos-immunopositive cells parallel to the optic tract in the mAMYG. From Dudley, C. A., Sudderth, S. B. and Moss, R. L. (1992), LHRH neurons in the medial septal-diagonal band-preoptic area do not project directly to the hippocampus: a double-labeling immunohistochemical study, *Synapse* 12, 139–146, with permission.

BNST, the nAOT, and the ventrolateral VMH. Female cervical stimulation or exposure of male rats to female-soiled bedding evoked a similar pattern of c-fos activation. In the male hamster, mating or exposure to vaginal discharge also produced activation of the vomeronasal system.

Activation of Gonadotropin-Releasing Hormone Neurons

During copulation, the female rat becomes more receptive over time and exhibits a release of LH (Figure 4). Because LH release is stimulated by GnRH, the chemosensory stimulation obtained during copulation is likely to activate GnRH neurons. Indeed, double-labeling immunocytochemical studies demonstrated that mating activated approximately 80% of the GnRH neurons, whereas after VNO removal only approximately 38% of the GnRH neurons were activated (see Figure 5). Similar studies

Figure 4 The effect of VNO removal in female rats. a, On lordotic responsiveness; b, on mating-induced luteinizing-hormone (LH) release. From Rajendren, G., Dudley, C. A. and Moss, R. L. (1990), Role of the vomeronasal organ in the male-induced enhancement of sexual receptivity in female rats, *Neuroendocrinology* **52**, 368–372, with permission.

from other laboratories also revealed an increase in the activation of GnRH neurons in the female mouse during mating and in the female rat during vagino-cervical stimulation. These observations provide firm evidence that chemosensory stimulation at the level of the VNO influences endocrine events at the hypothalamic level.

Vomeronasal Organ Response to Olfactory Stimuli and Olfactory System Response to Pheromonal Stimuli

Recent reports have indicated that cross-talk seems to exist between the vomeronasal system (VNS) and the main olfactory system. Although the VNO is mainly dedicated to sensing pheromones and the main olfactory epithelium that lines the nasal cavity senses common odors, recent findings make us rethink how pheromones control hormonal responses. This is particularly relevant for humans, in which adults lack a

Figure 5 GnRH-containing neurons that were activated by 3 h of repetitive mating in the female rat. a, Arrows point to GnRH neurons labeled immunofluorescently with Texas Red; b, arrows point to c-fos-immunopositive nuclei. In a, the five GnRH-containing cells also contained the c-fos protein. From Rajendren, G., Dudley, C. A. and Moss, R. L. (1993), Influence of male rats on the luteinizing hormone-releasing hormone neuronal system in female rats: role of the vomeronasal organ, *Neuroendocrinology* **57**, 898–906, with permission.

functional VNO. In mammals, mating and the reproductive behavior of females are controlled by GnRH neurons in the hypothalamus. GnRH is secreted into the hypophysial portal system, through which it regulates the action of gonadotropin-secreting pituitary neurons. Recent findings have brought the main olfactory system into the limelight in the pheromone and behavior field, not only by showing its crucial role in sexual and aggressive behavior but also by revealing a direct anatomical projection from the

main olfactory epithelium to luteinizing hormone-releasing hormone (LHRH) neurons in the hypothalamus, which regulate the gonadal hormone release. There is also evidence that the VNO in the sexually naïve male hamster is crucial for the female pheromone-induced mating behavior in male, but the main olfactory system takes over the functional role of the VNO in the context of sexual behavior. Thus, the traditional distinction that common odors are perceived through the olfactory pathway and pheromones by the vomeronasal pathway does not hold true; rather, the main olfactory system and vomeronasal system complement one another in chemosensory communication.

In the human fetus, a VNO develops and appears to guide the migration of GnRH neurons to the hypothalamus. However, the lack of a functional VNO in human adults does not imply that pheromone signaling does not occur in humans. Most of the vomeronasal receptor genes in the human genome are pseudogenes; however, four of these seem to be functional, of which one, hV1RL1, is expressed in olfactory mucosa and is likely to have a transducing function. At present, the only reproducible pheromonal effect in humans is the effectiveness of axillary secretions from women in different stages of their menstrual cycles to alter the cycle lengths of other women living in close proximity, thus causing menstrual synchronization. The recent findings in mice that the main olfactory pathway is required for reproductive behavior and that it projects to and activates hypothalamic GnRH/LHRH neurons might explain how organisms without a functional VNO, such as humans, use olfactory inputs in order to activate subcortical hard-wired circuits controlling innate sexual and reproductive behavior. Advances in neuroimaging have allowed us to visualize brain activity patterns in awake humans, and these techniques have shown that sex pheromones activate wide regions of the human brain, including areas traditionally thought to mediate cognition. These studies suggest that, as in the rodent, the pheromone-activated endocrine system is much more extensive than previously thought. Thus, it appears that we need to learn more about how intimately neuroendocrine functions, controlled by pheromones acting through our noses, might interact with other operations within the brain to control human behavior and cognition.

Stress and Reproduction

Social Interactions

Stresses of a social nature have the potential to exert negative effects on reproduction. The most common

social stress in animals of the same species is caused by high population density. Crowded conditions give rise to complex emotional states that may interfere with reproductive function. In addition, pheromonal cues emitted and detected in crowded conditions contribute to a decline in endocrine function. Although the exact mechanisms are uncertain, a wide array of noxious physical stimuli and distressed emotional states, including those of social origin, can enhance the activity of the hypothalamic-pituitary-adrenal (HPA) axis. The enhanced activity of this system is correlated with the suppression of reproductive processes at many levels in the reproductive axis. This suppression appears to be brought about by several specific actions that affect the GnRH system of neurons. First, corticotropin releasing hormone (CRH) and the proopiomelanocortin (POMC)-derived peptides adrenocorticotrophic hormone (ACTH) and β -endorphin can act in the brain to inhibit the release of GnRH. Second, corticosteroids themselves can decrease the responsiveness of the pituitary to GnRH. All these actions can interfere with the stimulatory effect of LH on steroidogenesis in the gonad. However, the extent of reproductive inhibition varies with social rank, sex, maturity, season, and some other factors.

The negative effect of emotional stress on reproduction is well illustrated in studies performed on cages of mice that are densely populated. Typically, a large cage is populated by a few pairs and the population is allowed to grow until it regulates itself. Maintaining this regulated population level often involves a marked inhibition of sexual maturation among young animals, as well as a cessation of reproduction by adults. In crowded deer mice, the effects of high population density on reproductive function are profound. When young deer mice are allowed to grow in pairs in small cages with adults of the opposite sex, they become fertile at 5–8 weeks of age. On rearing in dense populations, however, by 12–13 weeks of age, as many as 95% of these deer mice still are not fertile. According to Terman and colleagues, many die at well over 1 year of age without ever having achieved fertility. To some extent, pheromones can alleviate the negative effects of environmental stress on estrous cycling. Female mice housed in grouped, crowded conditions experience a lack of estrous cycling, which can be overcome by urinary cues from a conspecific male or by putative pheromones isolated from male mouse urine.

Agonistic Interactions

Intermale aggression in the form of fighting is common among densely populated animals. Losers of these

fight as well as other social subordinates and most of the onlookers seem physiologically stressed. Male mice fight to establish dominance even when only two are brought together. Agonistic interactions have been shown to have a profound impact on the endocrine system. The defeated animal experiences an almost immediate inhibition of LH secretion, lowered testosterone levels, and a dramatic rise in the secretion of corticosterone. Moreover, the increase in corticosterone can be conditioned to occur in response to the mere presence of a dominant male. Thus, even without the occurrence of overt fighting, subordinate animals may have depressed LH secretion. Such alterations in hormone levels may have negative consequences for health and fertility because the long-term hyperactivation of the HPA axis is related to a decline in immune system activity and reduced gonadal activity may result in sterility.

In higher vertebrates, behavioral responses to unfamiliar conspecifics are dependent on the actual environmental situation as well as social experiences made during behavioral development. Sapolsky's studies of a population of wild African olive baboons found that high- and low-ranking baboons differ in levels of cortisol and testosterone during periods of social instability, when overt aggression is quite common. Dominant males tended to have the lowest levels of cortisol. During periods of relative stability in the colony, differences in cortisol and testosterone between dominant and subordinate males were no longer detectable. Differences in cortisol levels appear to be extremely important, not only in terms of reproductive success but also in terms of survival. Males with the lowest cortisol levels survived the longest. A strong relationship exists among environmental factors (the rearing conditions as well as the actual situation), aggressive behavior, endocrine responses, and health.

Recently, two synthetic pheromones, 2,3-dehydro-*exo*-brevicomin (DHB) and 2-*sec*-butyl-dihydrothiazole (SBT), the urinary constituents in male mice, have been shown to elicit aggression in mice. The level of two other urinary constituents from male mouse, α - and β -farnesene, were elevated in the excreted urine of dominant male mice even several days after establishing dominance. The farnesene, absent in bladder urine but abundant in the preputial gland, when mixed with water or bladder urine significantly reduced the amount of time subordinate males investigated the urine deposits of dominant males. Thus, these four different urinary constituents have been shown to contribute to male-male agonistic interactions in mice.

Nonsocial Interactions

Reproductive events are also affected by stress encountered in nonsocial situations. The endocrine system appears to be more susceptible to emotional stress than to physical stress. For example, immobilized female rats display an immediate loss of LH pulsatile activity, but no change in pulsing was observed after an experimenter administered limb fracture. The stressful nature of immobilization has also been observed in cattle restricted for the first time by a stanchion, haltered, and prepared surgically for sequential blood collection via jugular cannulae. In these conditions, greatly elevated plasma cortisol levels and no pulsatile release of LH were noticed. However, repeated exposure to this procedure resulted in low levels of plasma cortisol and a normal episodic pattern of LH release.

Stress Signaling Mediated by Pheromones

Pheromone detection is an important component in the animal's ability to respond appropriately to stressful cues in social and agonistic interactions. It is well documented in several mammalian species that animals experiencing stress and fear release chemical signals that induce behavioral, endocrinological, and immunological changes in the recipient animals of the same species. Aggressive behavior is displayed in many species in day-to-day social interactions. This behavior is elicited by the appropriate recognition of an adversary as a potential threat or sexual competitor, and this recognition involves the detection of social odors by the VNS and/or olfactory system. The involvement of the VNS in such recognition is clearly demonstrated by several studies. Genetic ablation of the TrpC2 channel results in the failure of the male mice to display aggression toward other males, similar to behavior shown by male mice after vomeronasectomy, and also eliminates aggressive behavior of lactating female mice. However, in contrast, vomeronasectomy does not reduce the maternal aggression of lactating female rats. Vomeronasectomy also has been shown to decrease aggressive behavior in the male lesser mouse lemur, a prosimian.

In socially stressed crowded female rats, the removal of the VNO eliminates the resumption of estrous cycling induced by male rat urine. Mechanisms underlying the VNO-dependent responses to sociogenic stress are largely unknown at this time. Finding neural sites in which the stress-activated HPA axis interacts with the vomeronasal system seems a good strategy for determining where to begin research from a mechanistic point of view.

The Endocrine Response to Stress

General Overview of the Control of the Pituitary Gland

Neurohypophyseal Responses to Stress

Adenohypophyseal Hormones in Stress

Intermediate Lobe

Glossary

Neuroendocrine motoneurons

Hypothalamic nerve cells that produce and secrete neurohormones into the hypophyseal portal circulation and thus regulate the synthesis and release of anterior pituitary hormones.

Pituitary gland

The master gland of the endocrine system; as such, it mounts the primary endocrine response to stress, alongside the cells of the adrenal medulla, which are controlled by the autonomic nervous system.

The Endocrine Response to Stress

The stress response is characterized by marked changes of the levels of several hormones in blood. In the short term, the hormonal response to stress facilitates the mobilization of nutrients, e.g., breakdown of glycogen, promotes cardiovascular adaptation, e.g., increase of heart rate, the preservation of body fluid and salt, e.g., increase of salt reabsorption, as well as behavioral responses, e.g., explorative behavior. Exactly which hormone is responsible for a particular function may vary from species to species. For instance, the pituitary hormone prolactin is a hormone of salt-water balance in fish, while in mammals it is involved in the development of the breast in pregnancy and milk production during lactation. Of course, this latter process is a major strain on the osmotic balance of the mammalian organism, hence the phylogenetic traces of osmoregulation are evident, but only during breastfeeding and only in the female. Remarkably, prolactin is acutely released during stress in virtually all species, including male mammals; however, the functional significance of this response is still not understood.

If the stressor is chronic, i.e., recurs repeatedly or is never removed, the stress response may undergo habituation. However, in many cases this is not sufficient to prevent long-term detrimental changes of physical condition, such as reduced resistance to infectious agents, hypertension, and behavioral anomalies.

General Overview of the Control of the Pituitary Gland

The pituitary gland consists of three functionally and structurally distinct compartments ([Figure 1](#)).

The neurohypophysis or the posterior lobe is a large array of axon terminals and their supporting glial cells called the pituicytes. The neuronal perikarya that give rise to the terminal axons in the neurohypophysis lie in the hypothalamic paraventricular and supraoptic nuclei and form the magnocellular neurosecretory system ([Figure 1](#)). Separate populations of these cells produce the small peptide hormones vasopressin or oxytocin, which are synthesized in the cell bodies, transported along the axons, and released into the systemic circulation by the nerve endings in the neurohypophysis.

The adenohypophysis or anterior lobe contains various types of cells that are derived from the neural placode epithelium and produce polypeptide hormones for export into the systemic circulation. These hormones are fundamentally important for the control of the endocrine system. The cell types and their secreted hormones are as follows: corticotrophs, adrenocorticotropin (ACTH); mammothrophs, prolactin (PRL); somatotrophs, growth hormone (GH); somatomammothrophs, GH and PRL; thyrotrophs, thyroid-stimulating hormone (TSH); and gonadotrophs, luteinizing hormone (LH) and follicle-stimulating hormone (FSH). In addition, a further type of cell, the folliculo-stellate cells that are of mesenchymal origin, produce various cytokines and peptides that may be important for local paracrine control of the adenohypophysis.

The functional activity of the cells in the adenohypophysis is controlled by neurohormones (hypothalamic-releasing and -inhibiting factors) of hypothalamic origin. These are synthesized by neurons of the medial hypothalamus and secreted by axons that terminate in the external zone of the median eminence, which is a specialized neurovascular contact site at the base of the brain. This is called the parvicellular hypophyseotropic neurosecretory system of the hypothalamus ([Figure 1](#)).

Figure 1 Schematic representation of the hypothalamo-hypophyseal system that controls the secretion of ACTH. Cell bodies of parvocellular hypophysiotropic neurons synthesize corticotropin releasing hormone (CRH) and vasopressin (AVP) in the hypothalamic paraventricular nucleus (PVN). The axons reach the median eminence along an archlike pathway. The fibers first pass laterally above the fornix (F) and then turn ventral and caudal to reach the rostral part of the median eminence through the lateral retrochiasmatic area at the base of the brain, behind the optic chiasm (OC). Once in the median eminence, the fibers form terminal varicosities abutting on the pericapillary space in the external zone (EZ) of the median eminence. The effluent blood collects in the long portal veins and irrigates the anterior lobe of the pituitary gland. Magnocellular hypothalamic neurons in the PVN and the supraoptic nucleus (SON) produce AVP. The axons of these cells take a similar course in the hypothalamus as the parvocellular axons to reach the median eminence. In the median eminence, the magnocellular axons remain largely in the internal zone and appear to release AVP through conventional exocytotic mechanisms. AVP released in this manner is also found in hypophyseal portal blood. The coronal section of the median eminence shown here (median eminence detail) was stained with an antiserum against vasopressin-associated neurophysin and was prepared from the brain of an adrenalectomized rat. Adrenalectomy markedly increases the AVP content in the external zone. 3V, third cerebral ventricle; pm, magnocellular part of the PVN; mp, medial parvocellular compartment of the PVN.

The capillary blood vessels in the median eminence lie immediately adjacent to the parvocellular nerve terminals and have special large pores to allow diffusion of neurohormones released by the nerve fibers into the blood irrigating the median eminence. The venous effluent of the median eminence carries the hypothalamic hormones to the adenohypophysis, where the capillaries again branch out into smaller vessels, forming the pituitary portal system that irrigates the adenohypophysis. The transit time in this system from the nerve endings to the hormone producing cells is approximately 5 s.

The internal zone of the median eminence contains the varicose nerve fibers of the magnocellular neurons

running to the neurohypophysis. Functional evidence indicates that vasopressin and oxytocin are also secreted in the median eminence by these fibers in passage, thus neurohypophyseal secretions may also control anterior pituitary function.

In addition to hypothalamic and paracrine pituitary-derived factors, the function of anterior pituitary cells may also be influenced by factors reaching the adenohypophysis via the systemic circulation. For instance, steroid hormones produced and secreted by the adrenal cortex influence the synthesis and the release of ACTH. Cytokines derived from the immune system may also target these cells. The actions in the adenohypophysis of factors derived

from the endocrine target glands of anterior pituitary hormones are important for the formation of neuroendocrine feedback loops.

The intermediate lobe of the pituitary gland is composed almost entirely of cells that produce melanocyte-stimulating hormone, which is important in species that change their skin color rapidly as part of their adaptive response. The intermediate lobe is innervated directly by nerve fibers originating from the medial basal hypothalamus. It has no obvious functional anatomical communication with the other two lobes.

Neurohypophyseal Responses to Stress

Both vasopressin and oxytocin, the neurohormones released from the nerve terminals in neurohypophysis, have multiple functions in the body.

The principal function of neurohypophyseal oxytocin is the contraction of the uterus and the ejection of milk during breastfeeding. Actions on the kidney are controversial. Oxytocin may also contribute to the regulation of prolactin secretion by the adenohypophysis, as receptors and actions on prolactin release have been described. Some stressors, e.g., immobilization, increase the plasma levels of oxytocin in experimental animals; however, the importance of this in the stress response is not understood.

Vasopressin derived from the neurohypophysis increases blood pressure by contracting blood vessels, increases water reabsorption in the kidney (hence its other name, antidiuretic hormone [ADH]), and promotes glycogenolysis in the liver. The relative importance of these effects shows considerable species variation. In humans only the actions on the kidney appear relevant.

A further important action of vasopressin in the body is the stimulation of ACTH secretion. At physiological concentrations of vasopressin, this action appears to require a cohormone called corticotropin-releasing hormone (CRH). Vasopressin derived from the neurohypophysis is distributed in the systemic circulation and reaches levels required to influence ACTH release (0.1–2 nM) only in larger mammals (sheep, cat) where peripheral levels of vasopressin may reach 1–2 nmol/L. In rodents and humans, plasma levels rarely exceed 10 pmol/L. However, vasopressin released by the fibers of magnocellular neurons in passage through the median eminence and by their dendrites in the paraventricular nucleus (Figure 1) significantly contributes to the control of ACTH secretion.

The magnocellular neurons that produce vasopressin are often referred to as the osmosensitive neurosecretory system. It is important to bear in mind that

these neurons are osmosensitive in the widest sense of the word. On the one hand, changes of plasma osmolality will directly enhance the firing rate and secretory activity of these cells. On the other, conditions that potentially threaten osmotic homeostasis and body fluid volume such as strenuous exercise, pain, and hemorrhage all stimulate the release of vasopressin through neural afferent pathways.

Adenohypophyseal Hormones in Stress

The two main anterior pituitary hormones released by all types of stress are ACTH and PRL. While the physiological significance of ACTH in the stress response is firmly established, the role of PRL is not well understood. The stress-induced increase of plasma PRL is, however, important in the clinic as it poses a potential problem for the differential diagnosis of hyperprolactinemia of other causes, e.g., pituitary tumors.

Hypothalamic Control of ACTH

Like most midsize (39 amino acid residues) polypeptide hormones, ACTH is initially synthesized as a larger precursor molecule called proopiomelanocortin. In the anterior pituitary gland the main hormones derived from this precursor are ACTH and β -lipotropin. In target tissues such as the adrenal cortex extracellular proteases may cleave these hormones further to other biologically active fragments such as β - and γ -melanocyte-stimulating hormone.

The main mediators of the hypothalamic control of ACTH are CRH and vasopressin. CRH is produced by parvicellular hypophysiotropic neurons located in the medial parvicellular part of the hypothalamic paraventricular nucleus (Figure 1). These parvicellular neurons also produce vasopressin, which is co-packaged with CRH and co-released from the same secretory vesicles. Significantly, the relative amount of CRH and vasopressin synthesized and released by parvicellular neurons shows wide variation. In humans the level of vasopressin in parvicellular neurons increases with age. In experimental animals, vasopressin synthesis in parvicellular hypophysiotropic neurons may be enhanced from one- to twofold that of CRH to eight- to 10-fold CRH by various forms of chronic or repeated stress as well as adrenalectomy. This is somewhat paradoxical, as chronic stressors cause persistent increases of plasma corticosteroids whereas adrenalectomy brings about a drastic reduction of these hormones. The likely explanation for these findings is that the actions of corticosteroids on hypothalamic neurons are context dependent, i.e., are a function of the state of activation of other signaling pathways that regulate

the expression of vasopressin in parvicellular hypophysiotropic neurons.

As outlined in the previous section, the magnocellular vasopressinergic system is also involved in the control of anterior pituitary function. The innervation and regulation of these cells by afferent neural pathways are distinct from that of the parvicellular CRH neurons. However, the dendrites of vasopressinergic magnocellular neurons form synaptic contacts with CRH-containing parvicellular neurons, and vasopressin appears to influence the level of CRH in hypophysial portal blood. Thus, there is intrahypothalamic interaction between the magnocellular and parvicellular systems controlling the adeno-hypophysial secretion of ACTH. In addition, vasopressin derived from magnocellular axons in the median eminence is found in hypophysial portal blood.

A prominent functional interaction between CRH and vasopressin is evident at the level of the pituitary gland. CRH stimulates the release of ACTH through the intracellular messenger cyclic AMP. Vasopressin alone has little or no effect on ACTH release or cAMP synthesis, respectively, but synergistically enhances the effect of CRH on both ACTH release and cellular cAMP content. The basis of this is the augmentation of CRH-induced cAMP synthesis by vasopressin through protein kinase C. Thus, the adenylyl cyclase system of the adeno-hypophysial corticotroph cell appears to behave as a coincidence detector; it responds to vasopressin only in the presence of CRH. It is therefore likely that corticotroph cells express specialized adenylyl cyclase proteins (see **Adenylyl Cyclases and Stress Response**) that are activated by protein kinase C in the presence of the stimulatory G protein G_s . Indeed, two species of protein kinase C-stimulated adenylyl cyclase (isoforms 2 and 7) have been found in the adeno-hypophysis, and evidence for different pathways of cAMP biosynthesis induced by CRH alone and CRH and vasopressin in combination, respectively, has been reported. There are some species variations in the potency of CRH and vasopressin to stimulate ACTH. In the sheep, vasopressin appears to be the more potent ACTH secretagogue.

The significance of vasopressin in the control of ACTH release lies in the fact that in the presence of this neurohormone corticotroph cells become relatively resistant to the negative feedback action (see below) of adrenal corticosteroids. The opposition of glucocorticoid feedback is inversely correlated to the levels of cAMP, indicating that the intracellular levels of cAMP are major determinants of the efficiency of corticosteroid feedback inhibition at the pituitary level. The concentration of vasopressin required for inducing corticosteroid resistance is in the range of 1–2 nM, which requires either vasopressin derived

from magnocellular neurons or an increase of vasopressin expression and biosynthesis by parvicellular neurons such as that seen in chronic stress.

Peripheral and Paracrine Factors

The release of cytokines during inflammation appears to influence anterior pituitary ACTH release. For example, interleukin-1 induces ACTH secretion by an action in the brain and possibly directly on corticotroph cells. Of further interest is the production of leukocyte-inhibiting factor (LIF) and migration inhibitory factor (MIF) in corticotroph cells. LIF appears to be important for the maintenance of corticotroph functions, while MIF may attenuate corticosteroid feedback.

Corticosteroid Feedback Inhibition

Generally the plasma levels of adrenal corticosteroids are tightly controlled by a neuroendocrine feedback loop. Identified targets of corticosteroid action are adeno-hypophysial corticotrophs and parvicellular hypophysiotropic neurons that produce CRH and vasopressin. These are clearly sites of physiological relevance that control the final common elements of the neuroendocrine pathway that leads to the stimulation of ACTH. Under certain conditions, some of which are clearly pathological, glucocorticoid feedback inhibition is reduced. A well-characterized physiological example in humans is strenuous exercise. Cushing's disease and Nelson's syndrome are characterized by compromised glucocorticoid feedback at the pituitary level, which may be due to the tumoral transformation of corticotrophs. Furthermore, depressed patients have abnormally high levels of plasma corticosteroids and reduced feedback inhibition. In animals, chronic autoimmune inflammation produces high circulating levels of ACTH and corticosteroids. At the hypothalamic level this condition is characterized by a marked increase of vasopressin expression in parvicellular CRH neurons of the paraventricular nucleus. Furthermore, surgical stress and hemorrhage are also characterized by reduced corticosteroid feedback at the pituitary level, and it is known that under these conditions the magnocellular vasopressinergic neurons become active. Overall, this evidence indicates that vasopressin is mobilized in the short term as well as in the long term to modulate the efficiency of corticosteroid feedback inhibition of pituitary ACTH secretion.

Intermediate Lobe

The intermediate lobe is stimulated by epinephrine and norepinephrine derived from the adrenal medulla as well as by hypothalamic CRH. It is normally inhibited

by dopaminergic input from the arcuate nucleus. The physiological role of the intermediate lobe in adult humans is unclear. In rodents, stress induces the secretion of alpha melanocyte stimulating hormone (α -MSH), which is not susceptible to corticosteroid feedback inhibition.

Glossary

<i>Burnout</i>	Response to chronic work stress characterized by exhaustion, cynicism, and low feelings of accomplishment.
<i>Coping</i>	Responses by individuals to manage work stressors.

Work Stressors

In comparison with other occupations, police work has been identified as a particularly stressful occupation. Negative aspects of the job such as boredom,

Work Stressors

Psychological Burnout

Organizational Initiatives

Individual Initiatives

lack of respect from members of the public, excessive paperwork, contacts with the public that are sometimes negative and confrontational, shift work, threats of violence, and the militaristic nature of the bureaucratic structure of policing are among the work stressors that confront police officers. As a result of these and other stressful aspects of policing, a variety of symptoms and reactions may occur. These include deteriorating work performance (absenteeism, low morale), negative psychological states (emotional burnout, frustration, depression, anger), and psychosomatic and physical conditions (headaches, ulcers). The stresses of policing have been offered as one reason why capable police officers leave the profession for other careers.

Figure 1 shows the wide variety of potential stressors in police work. These include external demands and factors in the broader social context, aspects of the criminal justice system, the police organization and the police role itself, aspects of individual differences, and work–family issues. In addition, individual characteristics of police officers (e.g., authoritarian personality) may increase levels of work stress. Some of these stressors are common to a number of occupations while others are unique to police work.

The police organization and the police job pose particular demands. Police officers, particularly early in their careers, work varying shifts. In addition, they often are on-call. Overtime work is an inevitable part of their job. These factors result in heavy workloads in terms of hours per week spent working.

The police role also can be a concern. Police officers are required to be suspicious and hypervigilant. They are trained to exercise emotional control. Finally, their role conveys considerable authoritativeness. Police officers are always right and have considerable power and authority over citizens.

The peer culture and socialization influences in policing are also somewhat unique. These include the presence of masculine attitudes and values (e.g., control, dominance, authority), an extreme in-group/out-group mentality, and intense solidarity with peers. Police are likely to socialize with other police officers. Since many contacts with citizens are negative in nature, this fosters a mentality of us versus them.

Cynicism among police officers has received considerable attention as well. Officers begin their careers with positive attitudes toward their jobs and their role. These attitudes have been shown to steadily deteriorate as officers approach mid-career, then

Figure 1 Understanding stress in policing.

improve modestly with increasing police tenure as officers approach retirement. These attitude changes are important to both understand and manage since police officers are vulnerable to career plateauing given the steep organizational hierarchy in police management. The challenge for senior police management is to maintain positive attitudes among officers who will never be promoted.

These factors produce some common problem areas. Police officers become overinvolved with their force and underinvolved with their spouses or partners. The cynicism police have about their profession and the broader justice system spills over to the home front. Police officers make authoritative demands at home, as they do in their work. The irregular schedule and the leave time demands results in limited time with their spouses and families. Spouses or partners often have fear or anxiety about the safety of the officer. The spouses or partners are often jealous of the time that police officers spend with co-workers. Police families are sometimes isolated from the broader community. Finally, there are weapons in the home.

Work stressors in policing have been found to be related to work–family conflict, which in turn has been related to psychological burnout. Jackson and Maslach collected data from men and women in police work and their spouses or partners. They found that police officers' levels of burnout affected their interactions with their spouses and children. Burke examined antecedents and consequences of work–family conflict among 828 men and women in police work. Ratings of work–family conflict were weakly correlated with demographic antecedents but strongly correlated with work setting characteristics, levels of social support, levels of work and non-work stress, and several outcome measures (including burnout).

The combination of the types of individuals attracted to police work and the nature of the job has been suggested to increase particular problematic behaviors. These behaviors include anger, verbal outbursts, physical violence, alcoholism, and infidelity. Forty percent of police officers reported at least one episode of physical aggression during a conflict with their spouse or partner in the previous year.

Some published literature has downplayed the negative effects on officers of participating in risky calls and has pointed to the organizational structure as the greatest source of stress and pressure, adversely affecting job satisfaction and the perceived quality of life.

Although most police officers are men, an increasing number of women have become officers over the past decade. About 15 to 20% of officers in the developed world are women. Women and men in police work generally report similar levels of work

stressors, job satisfactions, burnout, and psychological well-being. Interestingly, the biggest source of job stress reported by women officers comes primarily from their male colleagues and to a lesser extent from male members of the general public. Women officers report prejudice, discrimination, and sexual harassment from both of these sources.

Psychological Burnout

Research attention has increasingly focused on psychological burnout, a common reaction to stress among police officers. Maslach and Leiter defined burnout as a syndrome of emotional exhaustion, depersonalization, and low personal accomplishment. Jackson and Maslach studied the effects of levels of self-reported psychological burnout on police officers' interactions with their spouses and children. Police officers reporting higher levels of psychological burnout were more likely to display anger, spend time off away from the family, be uninvolved in family matters, and have unsatisfactory marriages.

Empirical studies of psychological burnout among police officers have attempted to identify both individual difference characteristics and job conditions associated with higher burnout levels. Relationships of burnout with individual demographic characteristics are sometimes found but tend to be both inconsistent and weak. However, there is considerable evidence that work setting characteristics, particularly chronic work stressors, influence levels of psychological burnout. Such characteristics have included features of the job itself, quality of supervision, unmet expectations, and constraints in one's organizational environment.

Police forces are concerned when their officers use excessive force toward citizens. Recent research has shown a relationship between officer burnout levels and both attitudes toward the use of force and the actual use of force. Burned-out officers were more likely to advocate and use force and violence. Cynicism toward the general public lowers the threshold for using force or violence. Exhaustion and low professional efficacy reduce problem-solving skills while increasing use of force and violence.

Organizational Initiatives

Recruitment and Selection Interventions

Police work is a relatively high-paying occupation. As a result, a large number of individuals are interested in developing careers in policing. It seems desirable for police forces to use realistic job previews so that applicants have a greater understanding of the nature

and demands of the occupation, make greater use of personality assessment to weed out applicants likely to have a difficult time performing effectively, and use the training period to both socialize desired behaviors and identify applicants that may not perform well.

Counseling Interventions

It is critical to offer trauma counseling to police officers in cases of acute stress (using a weapon, shooting a suspect, death of a citizen in an accident). In addition, the provision of counseling to police officers via Employee Assistance Programs (EAPs) to handle alcohol abuse, work–family difficulties, and family problems is useful. The macho nature of the police culture and the real (or imagined) stigma of seeking help must be addressed.

Training Interventions

Two areas of training are evident. One specifically addresses work stressors and coping, particularly the use of active coping responses. Although such training has not been found to produce lasting benefits, it may still be justified. A second aspect of training, aimed at the organizational level, involves management development. It is unrealistic to expect that the nature and culture of policing will change dramatically or quickly, but efforts in this direction must be made.

Work–Family Initiatives

As noted earlier, the work–family interface can be particularly problematic in policing. Several work–family initiatives have been undertaken by innovative focus. These include a police spouse/partner support group, a couple workshop that both educates and addresses concrete issues, the inclusion of work–family content in training and development activities, and the use of peer counseling efforts.

Individual Initiatives

Although coping is a critical individual response to perceived work stressors due to its complexity, it is still not well understood. A simple taxonomy is to classify individual coping responses as active (problem solving, talk with others, anticipate upcoming

demands) or passive (do nothing, avoidance, use alcohol). Hurrell and Kroes reported that 25% of all police officers are dependent on alcohol as a stress reliever. In a large sample of police officers, Burke found that use of active coping responses was associated with greater job satisfaction, and use of passive coping responses was associated with greater psychological distress. Use of active and passive coping responses was, not surprisingly, negatively correlated. Police officers making greater use of active coping made lesser use of passive coping responses.

Glossary

<i>Arousal</i>	A cluster of PTSD symptoms that includes difficulty concentrating, sleep disturbance, irritability and anger, exaggerated startle response, and overalertness.
<i>Avoidance</i>	A cluster of PTSD symptoms that includes behavioral and cognitive avoidance (i.e., avoidance of thoughts, feelings, and reminders of the trauma), emotional numbing, loss of interest in activities, feeling disconnected from others, psychogenic amnesia, and a sense of foreshortened future.
<i>Cognitive-behavioral treatments</i>	A class of psychosocial treatment approaches focused on the interrelationships among thoughts, behaviors, and emotions.
<i>Posttraumatic stress disorder (PTSD)</i>	An anxiety disorder that develops in response to a traumatic event and is characterized by three clusters of symptoms: reexperiencing, avoidance, and physiological hyperarousal. PTSD is diagnosed after a 1-month period of sustained problems following the traumatic event.
<i>Reexperiencing</i>	A cluster of PTSD symptoms that includes reexperiencing the traumatic event through intrusive distressing thoughts, nightmares, flashbacks, and intense emotional upset and physiological arousal on exposure to reminders of the trauma.
<i>Trauma</i>	An event that a person experiences, witnesses, or learns about that involves actual or threatened physical injury or death and to which the person responds with feelings of fear, helplessness, or horror.

Overview of Posttraumatic Stress Disorder

Prevalence of Traumatic Events

According to the *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM-IV) a trauma is an event that involves actual or perceived physical threat or injury, to which a person responds with fear, helplessness, or horror. Although in the past, trauma was conceptualized as unusual and outside the realm of human experience, large epidemiological studies have demonstrated high rates of trauma exposure among adults. In a nationally representative sample of 6000 U.S. adults, Kessler and colleagues found that 60% of men and 51% of women reported experiencing at least one traumatic event in their lifetime. Similar findings emerged from Norris's 1992 study using a large, racially diverse sample – 74% of men and 65% of women reported experiencing at least one traumatic event. A lower prevalence of trauma was found in a sample of members of a health maintenance organization – 43% of men and 39% of women experienced a trauma in their lifetime. Taken together, these studies suggest that trauma is very common among adults in the United States.

Diagnostic Criteria of Posttraumatic Stress Disorder

The constellation of psychological difficulties that is observed most often following a trauma is called posttraumatic stress disorder (PTSD). PTSD is an anxiety disorder, and its symptoms fall into three clusters: reexperiencing the traumatic event (e.g., intrusive and distressing thoughts, flashbacks, and nightmares), avoidance of trauma-related reminders (e.g., avoiding thoughts or situations related to the trauma, emotional numbing, sense of foreshortened future), and hyperarousal (e.g., sleep disturbance, difficulty concentrating, irritability, and hypervigilance). In order to meet diagnostic criteria for PTSD, these difficulties must last for more than 1 month and cause substantial impairment in social or occupational functioning.

Prevalence and Course of Posttraumatic Stress Disorder

In the general population, the lifetime prevalence of PTSD is estimated to be around 9%. Estimates suggest that women are two times more likely to develop PTSD than men (e.g., 10% of women vs. 5% of men

in the general population). Because a diagnosis of PTSD requires an exposure to a traumatic event, rates of PTSD are inherently higher among those who have experienced such an event, with lifetime prevalence estimated at 25%. Among trauma survivors, the prevalence of current PTSD varies quite widely. For example, 15% of Vietnam combat veterans, 12–65% of female assault survivors, and up to 40% of survivors of serious motor vehicle accidents have been reported to meet diagnostic criteria for PTSD. Thus, although trauma exposure is quite common, persistent psychological difficulties in the aftermath of a traumatic event are less so and vary in frequency, in part, as a function of the traumatic experience.

In the initial days and weeks following a trauma, it is common to experience difficulties such as fear, disrupted sleep, and difficulty concentrating. Although most people experience such difficulties shortly after a traumatic event, the majority also experience a natural reduction in these difficulties over the following several months. Some trauma survivors, however, continue to experience significant PTSD symptoms for months and even years after exposure to the traumatic event. After 1 year, chronic PTSD is unlikely to remit without treatment; thus there is a critical need for effective treatments.

Cognitive-Behavioral Treatments for Posttraumatic Stress Disorder

Several cognitive-behavioral therapies for PTSD have been developed and tested in prospective randomized studies. These treatments include prolonged exposure therapy (PE), stress inoculation training (SIT), cognitive therapy (CT), cognitive processing therapy (CPT), and eye movement desensitization and reprocessing (EMDR). In this section, these treatments are reviewed and selected outcome studies that evaluate the efficacy of these treatments are presented.

Prolonged Exposure Therapy

Exposure therapy has been extensively evaluated as a treatment for persistent, pathological anxiety. The chief aim of this form of treatment is to help patients confront feared and avoided objects, situations, memories, and images until anxiety declines. PE for trauma survivors with PTSD is a treatment program that is based on the notion that avoidance of trauma-related memories and external reminders interferes with recovery from the traumatic event. Specifically, avoidance prevents opportunities to emotionally process the trauma memory, to learn to distinguish safe from unsafe situations, and to disconfirm erroneous trauma-related cognitions, thus maintaining the

unrealistic cognitions underlying PTSD that the world is utterly dangerous and that the trauma survivor is extremely incompetent in coping with stress. This view of the mechanisms involved in exposure therapy is central to emotional processing theory.

PE includes two forms of exposure: imaginal exposure and *in vivo* exposure. Imaginal exposure involves repeatedly recounting the traumatic memory. Specifically, the patient is instructed to vividly imagine the traumatic event and to describe it in detail aloud, along with the thoughts and feelings that occurred during the event. Imaginal exposure is typically conducted during several treatment sessions and via homework of listening to audiotapes of the in-session recounting of the memory. *In vivo*, or real-life, exposure involves systematic and repeated confrontation with safe or low-risk trauma-related reminders that evoke excessive or unrealistic anxiety. *In vivo* exposure is typically conducted outside of the treatment sessions as homework, during which the patient confronts situations, places, objects, or activities that are realistically safe but that trigger trauma-related fear and anxiety because they are related to the trauma. With *in vivo* exposure, the patient is encouraged to remain in the anxiety-provoking situation until his or her fear decreases by a significant amount. Other components of PE include psychoeducation about common reactions to traumatic events and breathing retraining.

Across several studies in different centers, PE has consistently been found to be highly effective. PE has demonstrated outcomes superior to supportive counseling (SC) and a wait-list control (WL). Most patients who receive PE experience a significant reduction in PTSD, depression, anxiety, anger, and guilt and experience improvements in overall functioning. In fact, in the treatment guidelines developed by experts in the field in conjunction with International Society for Traumatic Stress Studies (ISTSS), PE was identified as the most empirically supported intervention for PTSD.

Stress Inoculation Training

SIT was among the first of the cognitive-behavioral treatments to be applied to PTSD. According to the theory underlying SIT, stress occurs when people experience environmental events as exceeding their coping resources and thereby as threatening to their safety or welfare. Anxiety is a normal response to stress and signals people to increase efforts to cope with or somehow manage the stress-eliciting situation. In the case of individuals with PTSD, the anxiety evoked by trauma-related reminders is excessive and disruptive. Thus, SIT involves the learning and

repeated practice of specific coping skills, with the goal of helping patients to develop or enhance their ability to manage stress effectively and to reduce anxiety. Coping skills typically include tools such as breathing and relaxation training, guided self-dialog, assertiveness training, role-playing, covert modeling, and cognitive restructuring.

The efficacy of PE, SIT, SC, and WL were compared for female sexual-assault survivors with chronic PTSD. PE and SIT showed significant pre- to posttreatment reductions in reexperiencing and avoidance symptoms, whereas SC and WL did not. Also, at the end of treatment, 50% of patients who had SIT and 40% who had PE no longer met the criteria for PTSD; in contrast, only 10% of patients who had SC and none who had WL lost their diagnosis. At follow-up, there was a tendency for patients in the PE group to show further improvement in PTSD symptoms, whereas patients in the SIT and SC groups did not.

In a second study, the efficacy of PE and SIT was compared to the efficacy of a combination of both treatments (PE/SIT) and WL. All three active treatments resulted in considerable symptom reduction and were more effective than WL. However, PE appeared superior to the other treatments, leading to greater reductions of anxiety and depression, with fewer dropouts than both SIT and PE/SIT. At the end of treatment, 70% of patients who had PE, 58% who had SIT, and 54% who had PE/SIT lost their PTSD diagnosis compared to none in the WL group. At follow-up, women who received PE exhibited better social functioning than did those who received SIT or PE/SIT.

Cognitive Therapy

The aims of CT or cognitive restructuring (CR) for PTSD patients are to help patients to understand the role of their beliefs and appraisals of situations in influencing their emotional reactions, to identify trauma-related irrational thoughts or beliefs that trigger avoidance and/or excessive negative emotions (e.g., fear, shame, and rage), and to learn to challenge unrealistic beliefs and expectations in a rational evidence-based manner. In challenging these beliefs, evidence is weighed and alternative ways of viewing the situation are evaluated. In treatment sessions, and in daily life, patients practice responding to automatic thoughts and interpretations by reviewing the facts, considering alternative explanations, and sometimes experimenting with different ways of behaving in response to situations or events that elicit anxiety and other negative emotions. As a consequence, patients learn to evaluate whether their trauma-related beliefs and expectations accurately reflect

reality and are appropriate or helpful and modify them accordingly.

In a 2005 randomized trial, PE was compared with a program that included PE and CR (PE/CR) in female victims of sexual and nonsexual assault. The results suggest that both PE and PE/CR produce substantial improvements on multiple outcomes, including evaluator ratings of PTSD severity, depression, and social functioning. Similar to the PE/SIT findings, combining PE with CR did not improve the efficacy of PE. In an examination of PE in a sample of mixed trauma victims with chronic PTSD, Marks et al. compared PE to CR, PE/CR, and a relaxation control condition (R). The results suggest that PE, CR, and PE/CR are all quite effective and superior to R. Again, both PE and CR were effective, and combining them did not improve efficacy.

Cognitive Processing Therapy

Another cognitive behavioral therapy program for PTSD is CPT. CPT was originally developed for use with sexual assault victims and comprises elements of both CT and PE. Specifically, CPT includes CR around beliefs in five core areas – safety, power and control, esteem, trust, and intimacy – written exposure (i.e., writing about the traumatic memories and reading the account aloud to the therapist).

Resick et al. compared the efficacy of 12 sessions of CPT, 9 sessions of PE, and WL in rape victims with chronic PTSD. Results indicated that after 9 weeks of PE and 12 weeks of CPT, both treatments were highly effective in reducing PTSD; posttreatment only 19.5% of completers of CPT and 17.5% of PE met the criteria for PTSD. Among the completers, 76% of patients who had CPT and 58% of patients who had PE met the criteria for good end-state functioning (i.e., low PTSD and depression). Gains were maintained over time as well. At a 3-month follow-up, only 16.2% of those who received CPT and 29.7% of those who received PE were PTSD positive. Finally, at a 9-month follow-up, 80.8% of CPT and 84.6% of PE patients remained in sustained remission from PTSD symptoms. In sum, CPT appears to be an efficacious intervention for the short- and long-term treatment of PTSD. This study also provides further evidence for the efficacy of PE.

Eye Movement Desensitization and Reprocessing

EMDR emerged as a treatment for PTSD in the early 1990s, and since that time, a number of studies have investigated its efficacy. A core component of this intervention is theorized to be the therapist's repeated elicitation of rapid, saccadic eye movements (or other bilateral stimulation) from the patient during

the processing of traumatic memories. Shapiro theorized that rapid eye movements in some way override or reverse neural blockage or obstruction induced by the traumatic event. During EMDR treatment sessions, patients are asked to generate an image of the trauma and to focus on trauma-related thoughts, feelings, and/or sensations. Simultaneously, the therapist elicits the saccadic eye movements by having patients visually track a finger rapidly waved back and forth in front of their face. Other forms of laterally alternating stimuli (e.g., tapping or alternating sounds) are sometimes used rather than the original finger tracking. Patients are asked to evaluate the cognitions associated with these images and experiences and to generate alternative cognitive appraisals of the trauma or their behavior during the event. As patients focus on the distressing images and thoughts, and later focus on the alternative cognition, the saccadic eye movement (or another form of bilateral stimulation) is intermittently generated.

EMDR has been the focus of considerable controversy due to early claims regarding remarkable success in only a single session. Of the studies evaluating the efficacy of EMDR, more recent studies have typically used well-controlled designs and thus yielded clearly interpretable results. One well-controlled 1997 study evaluated the efficacy of EMDR relative to WL for PTSD in female rape victims. Three sessions of EMDR resulted in greater improvement of PTSD symptoms (57% reduction in PTSD at posttreatment) than WL (10% reduction at posttreatment). However, in contrast to other controlled studies, one therapist conducted all the treatments, and therefore the contribution of therapist and treatment effects are confounded. A direct comparison between EMDR and a combined treatment of PE plus stress inoculation training (called trauma treatment protocol, TTP) was conducted by DeVilly and Spence. Both TTP and EMDR reduced PTSD severity (63 and 46%, respectively), but TTP patients maintained their gains at follow-up, whereas EMDR patients showed higher rates of relapse (symptom reduction at follow-up of 61 and 12%, respectively). Rothbaum, Astin, and Marsteller compared PE, EMDR, and WL in female sexual assault victims. Compared to WL, both treatments resulted in a significant reduction in PTSD severity and related psychopathology. Immediately after treatment, only 5% of PE participants and 25% of EMDR participants continued to meet PTSD diagnostic criteria, compared to 90% of WL participants. The active treatments were significantly different from WL but did not differ from one another. At follow-up, however, significantly more participants receiving PE (78%) achieved good end-state functioning than did participants receiving EMDR

(35%). Taylor and colleagues compared PE, EMDR, and R and found that PE produced significantly greater reductions in reexperiencing and avoidance symptoms than EMDR and R, which did not differ from one another. Indeed, a 2001 meta-analysis found EMDR to be no more effective than exposure therapy programs and, moreover, suggested that the eye movements integral to the treatment and its underlying theory are unnecessary.

In summary, several cognitive-behavioral therapy programs have received empirical support for their efficacy in reducing PTSD severity and diagnosis in controlled studies: PE, SIT, CT, CPT, and EMDR. Studies that have attempted to combine these empirically supported approaches into new treatment packages to improve outcome have failed to demonstrate superior outcomes compared to the single-treatment protocols in these clinical trials.

Real-World Treatment Considerations

Treatment Tolerability and Preference

It also important to explore the tolerability and acceptability of empirically supported treatments for PTSD. Notably, although concerns have been raised by some clinicians and researchers that PE is too difficult to tolerate and may lead to symptom worsening and treatment drop-out, there is evidence that PE is tolerable. For example, Foa and colleagues examined self-reported symptom exacerbation in a sample of women with chronic assault-related PTSD who were receiving PE. After the first imaginal exposure, only a minority of participants in the study exhibited reliable symptom exacerbation during treatment: 10.5% reported an increase in PTSD symptoms, 21.1% reported an increase in anxiety, and 9.2% reported an increase in depression. Significantly, patients who reported such symptom exacerbation benefited from PE as much as those who did not report such exacerbation and were not more likely to drop out of treatment. Thus, although some patients experienced a brief period of exacerbation of symptoms during PE, this exacerbation decreased within 2 weeks and was unrelated to treatment outcome or completion. With respect to the completion of treatment, additional evidence supports that PE is tolerable. A 2003 review of dropout rates from various cognitive-behavioral therapy treatments for PTSD across 25 controlled studies indicated no significant differences in dropout rates among trials of PE, CT, SIT, EMDR, and combined treatments. PE did not produce a higher rate of treatment dropouts than other PTSD treatments; thus, concerns about excessive treatment dropout from PE appear to be unwarranted.

In fact, recent data demonstrate that treatments including PE are actually preferred over other psychosocial and psychopharmacological treatments. In a forced-choice comparison of treatment preference between PE and sertraline (an antidepressant medication) for PTSD, approximately 87% of female college students chose PE compared to only 7% who chose medication (6% chose no treatment). Consistent with these data, Tarrier and colleagues found that adults strongly prefer PE for PTSD compared to other psychosocial interventions, including EMDR, group therapy, and psychodynamic psychotherapy.

Treatment Dissemination

Disseminating empirically supported treatments such as PE to community-based clinicians is an important step in bridging the critical gap between research and practice for trauma survivors with PTSD. In one of the first studies to evaluate such dissemination, Foa and colleagues trained clinicians at a community-based rape crisis center in the delivery of PE for assault survivors with PTSD. These community clinicians provided treatment to a subset of participants in a randomized controlled trial, and their outcomes were compared to participants treated by those with expertise in PE at an academic medical center. After an initial training with follow-up consultation and supervision, results showed that the community mental health counselors obtained outcomes comparable to the university-based providers. This provides good evidence that empirically supported treatments such as PE can be successfully disseminated.

Childhood Sexual Abuse-Related Posttraumatic Stress Disorder

Despite the documented efficacy of PE for PTSD, there is some concern reported in the clinical literature that adults who have PTSD secondary to maltreatment during childhood, specifically child sexual abuse, may be a particularly vulnerable population for whom PE may be too difficult to tolerate. In response to this concern, a new treatment protocol, skills training affect and interpersonal regulation plus modified prolonged exposure (STAIR/MPE), was designed as a two-phase treatment, with phase 1 consisting of skills training in affect and interpersonal regulation and phase 2 consisting of modified PE (imaginal exposure plus coping skills training, with no *in vivo* exposure). Data suggested that STAIR/MPE resulted in significant reductions in PTSD and depression compared to WL. However, a critical weakness of this study is that this combination treatment was not compared to the usual PE. It is of note

that two recent clinical trials demonstrated that cognitive-behavioral treatments are effective for reducing PTSD among child sexual abuse survivors without a skills-building component. Moreover, a subanalysis of the data from Foa et al.'s 2005 study demonstrated that patients whose PTSD was related to child sexual abuse benefited from PE and PE/CR as much as did those whose PTSD was related to adult trauma. Thus, it seems that the skills-building component, which extends the number of treatment sessions and may delay recovery time, is unnecessary above the brief treatments that have empirical support.

Conclusion

Although exposure to potentially traumatic events is quite common, only a small minority of people develop persistent psychological difficulties such as PTSD in response to a trauma. The most validated types of treatment for PTSD are cognitive-behavioral therapies, and among the cognitive-behavioral therapy approaches available, PE has the strongest empirical support. Further, recent data suggest that PE is a preferred treatment among those who are given various treatment descriptions for PTSD. Concerns over the tolerability of PE, specifically that PE may lead to symptom exacerbation or premature dropout, are not supported by data. STAIR/MPE, a modified version of PE, has been shown to be helpful for childhood sexual abuse survivors with PTSD. However, this modified treatment has not been compared directly to already validated treatments for PTSD such as PE. Thus, at this point, we cannot determine whether it offers incremental benefit above such treatments. Future research should continue to evaluate ways to enhance treatment outcome and to disseminate efficacious treatments to a larger number of those who suffer with PTSD.

General Considerations

Physiological Measures

Brain Imaging

Glossary

α_2 -Adrenergic receptor A receptor for the neurotransmitter norepinephrine; largely expressed presynaptically and acts to inhibit further release of norepinephrine.

Adrenergic system The cells and pathways in the brain that use the neurotransmitter norepinephrine, either by releasing it or by expressing receptors that respond to it.

Corticotropin releasing hormone (CRH) A peptide neurotransmitter released by the median eminence of the hypothalamus to stimulate the hypothalamic-pituitary-adrenal axis. It also acts widely in the brain as a neurotransmitter.

Cortisol The primary glucocorticoid hormone.
Dendritic pruning Reductions in the branching dendrites of neurons, the part of the neuron that receives signals from other neurons.

Functional imaging The examination of the brain by magnetic resonance imaging or positron emission tomography, yielding cross-sectional images of the brain and highlighting areas of increased or decreased blood flow that reflect localized brain activity.

Glucocorticoids Steroid hormones, especially cortisol, that regulate metabolism and the stress response.

Hippocampus A brain structure crucially involved in complex memories (those available to consciousness).

Hypothalamic-pituitary-adrenal (HPA) axis

Longitudinal studies

The regulatory pathway from the brain to the adrenal cortex that regulates the release of cortisol.

Studies that follow the development of a disease in an individual over time, along with its biological correlates. By comparing variables before and after the development of a disease, these studies allow a stronger identification of the pathological effects of the disease process than other types of studies.

A serotonin agonist.

Metachlorophenylpiperazine (m-CPP)
Naltrexone
Opioid system

An antagonist of opioids receptors.

The cells and pathways in the brain that use endorphins, or endogenous opioids, as neurotransmitters, either by releasing them or expressing receptors that respond to them. These are the same receptors that bind opium and other opioid drugs.

Provocation studies

Studies that use drugs or environmental stimuli (e.g., stories, images, or tasks) to provoke a specific brain response.

Serotonin system

The cells and pathways in the brain that use the neurotransmitter serotonin, either by releasing it or by expressing receptors that respond to it.

Structural imaging

The examination of the brain using high-resolution magnetic resonance imaging (or, in the past, computed tomography) to carefully quantify the size of identifiable structures.

Twin studies

Research comparing identical twins, one of whom suffers a pathology, such as posttraumatic stress disorder. Because the healthy twin is genetically identically and shares much the same environment as the patient, the similarities in his

brain structure or function to that of the patient, which differ from the average population and are similar to the patient population, suggest a preexisting condition or vulnerability to disease.

Yohimbine A pharmacological antagonist of α_2 -adrenergic receptor.

General Considerations

In general, two approaches have been used to examine the neurobiological basis of posttraumatic stress disorder (PTSD): imaging and biological measures. Imaging has been used to examine the anatomy of the brain and its activity both at rest and during a number of symptom provocation and cognitive challenges. Biological measures have been used to measure a number of candidate hormonal and neurotransmitter systems, again, both at rest and after symptom provocation. We consider some of the findings of these studies here.

It is important to remember that most studies of PTSD compare PTSD patients to normal controls. Such studies cannot differentiate between a finding in the PTSD patient that is the result of the disease process of PTSD and follows the traumatic event and a finding that preceded the trauma and thus may indicate a source of vulnerability to PTSD. Only longitudinal and twin or family studies can effectively differentiate between those possibilities, and there have been few such studies to date.

It is likely that preexisting factors, whether genetic or acquired from previous experience, are crucial to the development of PTSD. Exposure to trauma is not enough, no matter how severe. Only a small proportion of people exposed to trauma, even horrific trauma, develop PTSD. In the United States, approximately 90% of the population is exposed to at least one traumatic event serious enough to satisfy the trauma criterion for PTSD. However, only approximately 8% of the population develops PTSD. This means that it is particularly important to understand the neurobiological factors that contribute to vulnerability to PTSD or to its inverse, resiliency.

One obvious biological factor that seems to play a role in vulnerability to PTSD is sex. Women are twice as likely to develop PTSD after a trauma than men, although the interaction between biology and type of trauma is a complicated one. Women are much more likely to develop PTSD after an assault and men are much more likely to develop PTSD after being raped (even though their risk of rape is lower); both sexes have an equal risk of PTSD after natural disaster. These patterns suggest that the differences in rates of PTSD between men and women overall have

something to do with the meaning of the type of trauma to each sex. Both sexes suffer equally from natural disasters, which affect everyone in the area, whereas physical or sexual assault emphasizes the relative weakness of the victim.

PTSD is, by definition, a chronic condition in which symptoms persist for at least 1 month. However, in the immediate aftermath of a trauma, almost everyone experiences symptoms of PTSD. Thus, the symptoms of PTSD are almost certainly part of the normal human response to stress. It is the failure of recovery that is characteristic of PTSD, so it may be that the right place to look for vulnerability is in the mechanisms of recovery. Such mechanisms may include biological mechanisms, such as the glucocorticoid response to stress, or psychological mechanisms, such as the ability of people to suppress fearful responding in the short term through inhibition by prefrontal cortex or in the long term through behavioral extinction or desensitization of fearful responses to the reminders of the trauma.

Physiological Measures

Frightening experiences elicit a characteristic stress response. The faster response to a frightening stimulus is the adrenergic stress response, which orchestrates the readiness of an animal or a human to protect itself, the fight-or-flight response originally described by Walter Cannon. Simultaneously, a second, slower stress system is activated, the hypothalamic-pituitary-adrenal (HPA) axis, which results in the production of the effector glucocorticoid cortisol, as first described by Hans Selye. One important action of the slower cortisol response is to shut down or limit the adrenergic response.

Disruptions in stress hormone regulation stand out prominently in the neurobiology of PTSD. Some of the first studies of PTSD patients indicated not only that PTSD patients show increased excretion of epinephrine and norepinephrine at baseline but also that adrenergic system is hyperreactive. The administration of yohimbine to PTSD patients provided the most striking demonstration of the increase of adrenergic tone and its relation to PTSD symptoms. Yohimbine blocks the α_2 receptors for norepinephrine. These receptors are presynaptic on adrenergic terminals and act like a thermostat to inhibit the release of norepinephrine into the synapse. The administration of yohimbine is mildly anxiogenic in normal controls, but in PTSD patients it caused great distress, precipitating flashbacks in 40% and panic attacks in 70%, whereas none of the controls experienced either. These data indicate a profound dysregulation of the adrenergic system. Interestingly, yohimbine

also provokes panic attacks in patients with panic disorder but not in patients with schizophrenia, depression, obsessive-compulsive disorder, or generalized anxiety disorder and also not in normals. Thus, PTSD may share some part of its pathophysiology with panic disorder.

Increases of adrenergic tone and reactivity may be of great importance in the symptomatology of PTSD. It is clear from the experiment that increases of adrenergic neurotransmission may be precipitating some of the most troubling symptoms of PTSD, including not only flashbacks and the physiological hyperreactivity characteristic of panic attacks but also intrusive thoughts, emotional numbing, difficulty concentrating, and increased startle. However, it has also been extensively demonstrated in preclinical studies that the adrenergic system is crucial to memory strength, and particularly to the establishment of fearful or distressing memories. This explains in part why memories of frightening events are so vivid. Thus, high levels of norepinephrine during traumatic experiences may well strengthen the formation of distressing memories and make them more vivid for PTSD patients.

When challenged with yohimbine, the family members of PTSD patients do not have more panic attacks than normal subjects, whereas the healthy family members of panic disorder patients do have high rates of panic attacks upon yohimbine challenge. This suggests that a hyperreactive adrenergic system may be a predisposing factor for panic disorder, whereas the adrenergic hyperreactivity of PTSD patients may be acquired.

What might account for that hyperreactivity? One hypothesis is an insufficient regulation by an inadequate glucocorticoid response. We might expect from the strong response to trauma in PTSD patients that cortisol levels, as part of the stress response, should be high. In fact, most studies have found that glucocorticoid levels are low at baseline in PTSD patients and that the feedback inhibition of glucocorticoid synthesis is overly strong. Thus, when injected with an exogenous glucocorticoid, dexamethasone, patients with PTSD suppress the production of endogenous cortisol for a significantly longer time than normal controls. This is true even though the levels of the hypothalamic hormone that drives cortisol synthesis and release, corticotropin releasing hormone (CRH), are high in PTSD patients.

By contrast, in depression, high CRH levels drive high levels of circulating cortisol. The contrasting pattern in PTSD suggests that feedback inhibition of the HPA axis is dominant over CRH drive. Low circulating levels of cortisol may well allow the adrenergic response to stress to run out of control. But

are these low levels in PTSD patients the result of a burnout of the cortisol system by sustained high cortisol during and after the trauma?

Two longitudinal studies of motor vehicle-accident victims have addressed this question. In one study, 15-h urinary cortisol excretion was measured after accidents; in the other, cortisol levels were measured in blood samples drawn on the way to the emergency room. In both studies, the victims who went on to develop PTSD had significantly lower cortisol after their accidents than those who did not. Thus, even just after their trauma, the cortisol levels of those who later went on to PTSD were lower. This begins to hint that lower cortisol in PTSD patients may not be the result of burnout after prolonged elevations around the time of trauma but rather a preexisting state that contributes to a vulnerability to PTSD.

This preexisting state is almost certainly not entirely genetic. For example, in rape victims, cortisol levels after the rape were lower in those who had sustained a previous assault, and the victims of previous assaults were three times as likely to go on to develop PTSD. Women who had no previous trauma had cortisol levels that averaged three times higher than those who did and had higher cortisol levels when the index rape was more severe. Women with previous trauma showed no increase in cortisol levels in response to increased severity of rape.

However, the question remains whether low cortisol levels existed even before the rape. By comparing the children of Holocaust survivors to children of European Jews who escaped the Holocaust, Rachel Yehuda and her colleagues have examined this question. The children of Holocaust survivors are almost four times as likely to develop PTSD as the controls. The children of Holocaust survivors show lower cortisol excretion than do the controls, which argues for a preexisting defect in the cortisol system. However, this group was not homogeneous. When neither parent nor child had PTSD, cortisol excretion was the same as that of controls. However, when the parent had PTSD, the cortisol excretion was lower in the offspring; it was lowest when both parent and child had PTSD. Thus, it is clear that low PTSD levels are a preexisting risk factor that may not only be due to previous trauma. It is tempting to think that this risk factor is due to the transmitted anxiety of parents with PTSD, acting like a previous assault in rape victims to lower cortisol. However, there remains a potential for a genetic explanation. It might be that the Holocaust survivors with PTSD also had low cortisol as a risk factor for their PTSD and transmitted that risk genetically rather than behaviorally.

All of these data on endocrine stress responses outline one potential chain of causation in generating

the clinical picture of PTSD. A hypoactive cortisol response may lead to the dysregulation of the adrenergic stress response. An ungoverned adrenergic system may increase the intensity of traumatic memories, the strength of association of those memories with a wide range of stimuli in the environment, and the physiological and psychological arousal when those memories are recalled.

Beyond the alterations in the endocrine stress responses, other physiological abnormalities have been identified in PTSD patients. Endogenous opioids are low in PTSD sufferers, who also show a reduced pain threshold. However, when exposed to traumatic reminders, Vietnam veterans with PTSD showed a higher pain threshold that could be reversed by naltrexone (which blocks opioids receptors). Thus, PTSD patients appear to have both decreased resting levels of endogenous opioids and a more reactive opioid system. This may lead to cycles of trauma reminders inducing numbing, followed by opioid withdrawal (and PTSD) symptoms such as irritability and disturbed sleep. Because these hyperarousal symptoms of opioid withdrawal may be mediated by adrenergic activity, low tonic opioid levels may act in concert with low cortisol to increase adrenergic reactivity.

One study examined the effect of a serotonin agonist metachlorophenylpiperazine (m-CPP) on PTSD patients compared with the effect of yohimbine and placebo. As in the studies of yohimbine, m-CPP caused panic attacks in a substantial number of the patients, along with exacerbations of other PTSD symptoms. A similar number of patients experienced panic attacks and worsened PTSD symptoms after m-CPP injections. Interestingly, different subsets of patients tended to get panic attacks with the two agents. Another study showed that PTSD patients had a higher frequency of being homozygous for the short allele of the serotonin promoter, a genotype associated with depression after life stressors. Thus, although fewer data indicate a role for serotonergic than for noradrenergic mechanisms, serotonergic mechanisms may make a second and possibly independent contribution to PTSD vulnerability or pathophysiology.

Brain Imaging

Three areas of the brain have received particular attention in imaging studies of PTSD, because there are *a priori* reasons to suspect their involvement. The hippocampus has been examined in detail because a wealth of preclinical studies indicate that chronic stress has profound effects on this structure. The amygdala has been examined because this brain structure has an orchestrating role in all fear learning. Finally, the

prefrontal cortex has been examined because of its role in suppressing amygdaloid activation.

Structural Imaging

A variety of studies in animals indicate that elevated levels of the stress hormone cortisol is damaging to the hippocampus. Long-term exposure to exogenous glucocorticoid steroids and prolonged stress (which presumably elevates endogenous levels of these steroids) both damage the CA3 region of the hippocampus and cause dendritic pruning of neurons there, with the net effect of decreasing hippocampal volume. Although lower levels of cortisol are usually observed in PTSD patients, it is reasonable to hypothesize that cortisol levels might have been extremely high at the time of traumatic exposure.

Consistent with this hypothesis, hippocampal volumes in PTSD patients are decreased compared to controls in a number of structural imaging studies of combat veterans and of adult victims of childhood sexual abuse that compared PTSD patients to others exposed to combat or sexual abuse without PTSD. However, results have been less consistent with other patient populations and have not been observed in Holocaust survivors or patients with personality disorders who suffer from PTSD.

These studies are cross-sectional, comparing PTSD patients to controls, and do not address whether the hippocampal volume deficits might predate the trauma and development of PTSD. One study of identical twins in which one twin was a Vietnam combat veteran addressed this question indirectly. This study found that smaller hippocampal volume in the combat-exposed twin correlated to the severity of his PTSD symptoms. However, the hippocampal volume of the non-combat-exposed twin correlated just as closely with the severity of his brother's symptoms. These data suggest strongly that small hippocampi are a risk factor for, rather than a result of, combat exposure. Two longitudinal studies have also addressed this question, and neither found decreases of hippocampal volume associated with the development of PTSD or with ongoing PTSD pathology. Similarly, no changes in amygdala volume have been seen in PTSD patients.

Functional Imaging

Brain structure may be of less importance than brain function in psychiatric disease, including in PTSD. Functional imaging, looking at brain activity as reflected by blood flow, may thus be a better indicator of pathological brain function, especially when performed using biological or psychological probes designed to stimulate functional systems. Functional

studies have focused attention on the amygdala, a brain region important for orchestrating the fear response, as well as in related paralimbic and frontal structures. This approach remains in its early stages, and a clear anatomical pattern has not yet emerged, perhaps because of the wide variation in patient populations and provocation protocols in use.

One interesting approach has been to use pharmacological provocation with yohimbine, the antagonist of inhibitory presynaptic α_2 autoreceptors. As previously described, yohimbine, when injected into PTSD patients, exacerbates symptoms and causes panic attacks and flashbacks. In a positron emission tomography (PET) imaging study, yohimbine injections tended to increase metabolism in a variety of cortical regions including the prefrontal, temporal, parietal, and orbitofrontal cortices in control subjects, but tended to decrease metabolism in those regions in PTSD patients. These data indicate that the adrenergic dysregulation observed in PTSD patients profoundly changes brain activation patterns and suggests a role for those brain structures with changed activity in suppressing the set of symptoms evoked by yohimbine, specifically panic attacks and flashbacks.

Psychologically driven provocation studies have generally shown differences in brain activation between PTSD patients and controls, although these have not always been consistent. Left amygdala activity was increased by combat sounds, compared to white noise, in Vietnam veterans with PTSD but not in combat-exposed veterans without PTSD or in normal controls. In another similar study with combat sound, veterans with PTSD showed activation of the right amygdala as well as in other regions. In another comparison of veterans with and without PTSD who were asked to visualize combat, the veterans showed activation in the right amygdala as well as in the ventral anterior cingulate gyrus. However, when actually viewing combat images, no such activation was seen; however, PTSD patients showed decreased activity in Broca's area, an area important for language generation.

Trauma scripts and viewing of traumatic images have generally not yielded amygdala activation, whereas visualization and simple stimuli, such as combat sounds, which bypass the cortex, effectively activate that structure. Interestingly, masked presentations of fearful faces, too brief to register consciously, caused exaggerated amygdala responses in veterans with PTSD compared to healthy veterans.

On the other hand, script-driven provocation has effectively activated the posterior cingulate and motor cortex in women with a history of childhood

sexual abuse with PTSD compared to those without PTSD. Women with PTSD also failed to activate Broca's area and the anterior cingulate compared to controls, who did.

In summary, the functional imaging data so far do support changes in the function of the amygdala and of the limbic and prefrontal cortices in PTSD. However, the exact nature of those changes and their significance in the symptomatology and pathophysiology of PTSD remain to be defined.

Assessing Posttraumatic Stress Disorder Symptoms in
Children

Glossary

*Avoidance or
numbing*

Refers to symptoms of posttraumatic stress syndrome (PTSD), such as avoiding thoughts, feelings, or conversations about the traumatic event, avoiding reminders of the event, diminished interest in normal activities, or feeling detached or removed from others.

Hyperarousal

Refers to symptoms of PTSD, such as difficulty sleeping or concentrating, irritability, angry outbursts, hypervigilance, and an exaggerated startle response.

Life threat

The perception that one's life is in danger; it is a key aspect of exposure to traumatic events, and is believed to be critical for the emergence of PTSD and related symptoms.

*Loss and
disruption*

Loss (of family and friends, of personal property and possessions) and disruption of everyday life (displacement from home, school, or community); it is also an aspect of exposure to traumatic events and can contribute to PTSD in children.

Re-experiencing

Refers to symptoms of PTSD, such as recurrent or intrusive thoughts or dreams about the event, or intense distress at cues or reminders of the event.

Posttraumatic stress disorder (PTSD) refers to a set of symptoms that develop following exposure to an unusually severe stressor or event. Typically, the event is one that causes or is capable of causing death, injury, or threat to the physical integrity of oneself or another person. In order to meet criteria for a diagnosis of PTSD, a child's reaction to the traumatic event must include intense fear, helplessness, or disorganized behavior. In addition, specific criteria for three additional symptom clusters must be met: re-experiencing, avoidance/numbing, and hyperarousal. Re-experiencing includes symptoms such as recurrent or intrusive thoughts or dreams about the event and intense distress at cues or reminders of the event; for young children, re-experiencing also may be reflected in repetitive play with traumatic themes or by a re-enactment of traumatic events in play, drawings, or verbalizations. Avoidance or numbing includes symptoms such as efforts to avoid thoughts, feelings, or conversations about the traumatic event, avoiding reminders of the event, diminished interest in normal activities, and feeling detached or removed from others. Hyperarousal symptoms include difficulty

sleeping or concentrating, irritability, angry outbursts, hypervigilance, and an exaggerated startle response; these behaviors must be newly occurring since the event. For a diagnosis of PTSD, the above symptoms must be manifest for at least 1 month, and be accompanied by significant impairment in the child's functioning (e.g., problems in school, friendships, or family relations). In addition, acute PTSD is specified if the duration of the symptoms is less than 3 months; chronic PTSD is specified if the duration of symptoms is 3 months or longer.

Traumatic Events

In recent years, media coverage of devastating natural disasters, bombings, and terrorist activities has drawn attention to the significant trauma that children and adults experience following such events. It has become increasingly apparent that exposure of children to such traumatic events may lead to reactions that interfere substantially with their day-to-day functioning and cause them significant distress. Specifically, exposure to natural disasters (e.g., hurricanes, tsunamis, tornadoes, fires, earthquakes, or floods) and to human-made disasters and acts of violence (e.g., plane crashes, sinking of ferries, war, terrorist attacks, bombings, sniper shootings) represent traumatic events that may result in the emergence of PTSD. Although considerable attention has been devoted to the effects of terrorism and community-wide disasters, it is also the case that children who experience motor vehicle accidents, life-threatening illnesses or medical procedures, or violence of a personal nature (e.g., physical and sexual abuse, rape, kidnapping, and community violence) also are vulnerable to developing PTSD. This article describes common symptoms of PTSD in children and factors that contribute to the development and course of this disorder.

Posttraumatic Stress Disorder in Children: Clinical Picture

The diagnostic category of PTSD was introduced in the third edition of the American Psychiatric Association's *Diagnostic and Statistical Manual of Mental Disorders* (DSM-III). At that time, PTSD was primarily considered to be an adult disorder. More recently, there has been a growing awareness that children and adolescents also experience PTSD, which is reflected in the current edition of the DSM (DSM-IV). (See previous description of the criteria for the disorder.)

Community studies of children following traumatic events suggest that the most commonly reported PTSD symptoms are those of re-experiencing the

event. For example, up to 90% of children exposed to a catastrophic hurricane reported symptoms of re-experiencing 3 months after the disaster. In contrast, symptoms of avoidance and numbing are far less common in children and, in fact, their presence may be a good indicator of PTSD.

Due to their limited verbal capacity, the diagnosis of PTSD is especially difficult in very young children, such as infants, toddlers, and early preschoolers. In such cases, generalized anxiety, fears, avoidance of certain situations that may be linked to the traumatic event, and sleep disturbances may be useful indicators of PTSD.

PTSD may also be present (i.e., co-morbid) with other psychological difficulties. In particular, PTSD often is co-morbid with anxiety disorders (i.e., separation anxiety disorder, specific phobias, generalized anxiety disorder, panic, and agoraphobia) and with affective disorders (e.g., major depressive disorder and dysthymia). Traumatic events that involve the loss of loved ones (e.g., earthquakes and bombings) are especially likely to lead to depressive reactions in children.

Prevalence and Developmental Course

Prevalence

It is difficult to estimate the prevalence of PTSD in children and adolescents because studies have been extremely diverse with respect to the type of trauma evaluated, assessment methods used, and the length of time that passed since the traumatic event occurred. Community studies suggest that approximately 24–39% of children and adolescents exposed to trauma (e.g., community violence or a natural disaster) meet criteria for PTSD. Rates of PTSD have been reported to be even higher among children and adolescents who witness death or physical injury in conjunction with acts of violence or following disasters associated with mass casualties.

When subclinical levels of PTSD are considered, up to 55% of the children in large community samples have reported at least moderate levels of PTSD symptoms during the first 3 months following a traumatic event, such as a hurricane. Thus, symptoms of PTSD appear to be common among children exposed to trauma, although fewer children and youth will meet criteria for a PTSD diagnosis.

Developmental Course

Little is known about the course of PTSD symptoms in children over time. However, it does appear that PTSD symptoms may emerge in the days or weeks

following a traumatic event, and can take months or years to dissipate in some children. In the absence of re-exposure to trauma or of the occurrence of other traumatic events, the typical developmental course of symptoms appears to be one of lessening frequency and intensity over time. For example, 3 months after a highly destructive natural disaster (Hurricane Andrew: a Category 5 hurricane, that struck South Florida in 1992), 39% of the children informally met criteria for PTSD disorder, but this was reduced to 24% at 7-months postdisaster, and to 18% by 10-months postdisaster. A subgroup of children who reported moderate-to-severe PTSD symptoms was followed 42 months postdisaster, revealing that 40% continued to report moderate-to-severe PTSD symptoms as well as impairment in their functioning; yet, almost none of the children who had mild or no symptoms at 10-months postdisaster reported any symptoms later on. Similarly, 51.5% of the adolescents who survived the sinking of the cruise ship *Jupiter* in 1988 (with 400 British school children on board) developed PTSD after the disaster, but 5–8 years later, only 17.5% still had PTSD.

These data suggest a steady reduction in the frequency and severity of PTSD and its symptoms over time (with no further exposure to similar trauma), although a significant minority of children and adolescents do not recover and continue to report substantial difficulties years later. The findings also indicate that it is highly unusual for children and adolescents to report significant symptoms of PTSD 1 year or more after a traumatic event, if they did not experience such symptoms closer to the event. Although there may be a brief period of shock or numbing, or sometimes elation and relief at still being alive, most children who develop PTSD will evidence stress symptoms within the first few months of the traumatic event.

Persistence of Symptoms

Overall, findings confirm that children's reactions to disasters and other traumatic events are not merely transitory feelings that dissipate quickly. On the contrary, they appear to linger and persist and are likely to cause distress to children and their families for some time. One factor that contributes to the persistence of PTSD symptoms in children over time is the occurrence of other significant life stressors. Children who encounter major life stressors (e.g., a death or illness in the family or parental divorce) in the months following a traumatic event, do not recover quickly, and report persistently high levels of PTSD symptoms over time.

Demographic Trends

Gender and Age

Some studies indicate that PTSD appears more frequently among girls than boys, but this has not consistently been the case. Preadolescent children may be more vulnerable to PTSD than older youths, although it is difficult to draw generalizations regarding children's vulnerability to PTSD at different ages, as findings on age-related differences have been inconsistent and may be influenced by diverse developmental manifestations of PTSD.

Ethnicity

PTSD appears to occur across diverse ethnic and cultural groups. Community studies suggests that minority youths exposed to severe natural disasters report more symptoms of PTSD and have a more difficult time recovering from such events than nonminority youths. It is possible that socioeconomic factors might account for such findings, in that children and families from minority backgrounds may have less financial resources or less adequate insurance to deal effectively and efficiently with the postdisaster rebuilding process. This could prolong the period of life disruption and loss of possessions that ensues after destructive natural disasters.

Factors that Precipitate Posttraumatic Stress Disorder in Children

Exposure to Trauma

A wide range of traumatic events have been linked to the emergence of PTSD in children and adolescents. However, two key aspects of exposure to these traumatic events are thought to contribute to children's reactions: the presence or perception of life threat, and personal loss and disruption of everyday events.

The presence or perception of life threat is considered to be essential for the emergence of PTSD. It is easy to understand why children who witness or are exposed to acts of violence, such as sniper shootings or severe physical abuse by a caretaker, feel that their life is in danger. It is also the case, however, that catastrophic natural disasters or personal disasters (such as residential fires) can elicit perceptions of life threat in children, even if no one is injured or hurt. For example, although very few lives were lost in South Florida as a result of Hurricane Andrew, the extensive destruction of homes and property that occurred during the storm was terrifying to many children and adults. In one study, 60% of the children interviewed "thought that they were going to die"

during the storm. Thus, perceptions of life threat can occur in the absence of actual loss of life or serious injury.

Evidence also underscores the importance of loss (of family and friends or personal property and possessions) and disruption of everyday life (displacement from home, school, or community) as contributing to PTSD in children. The life changes that result from this aspect of exposure to a traumatic event also predicts PTSD symptoms in children and adolescents.

The duration and intensity of life-threatening events are additional aspects of traumatic exposure associated with children's PTSD symptom severity. The prolonged nature of certain traumatic events (e.g., floods or child abuse) is very distressing to children when no immediate relief is in sight.

Role of Prior Psychological Functioning

Children with pre-existing psychological problems, especially anxiety, may be more vulnerable to developing PTSD following traumatic events. For example, children's anxiety levels 15 months before a traumatic event have been found to predict their levels of PTSD symptoms 3 and 7 months postdisaster, even when controlling for children's exposure to the event. This suggests that anxious children may have a vulnerability to PTSD, even if their degree of exposure to a trauma is relatively low. In addition, children who had greater levels of exposure to the disaster (i.e., more life threat or more loss/disruption) showed an increase in anxiety symptoms following the disaster relative to children with less disaster exposure. Other studies have shown predisaster levels of depression predicted postdisaster PTSD among adolescents exposed to a destructive natural disaster (earthquake).

Aspects of the Recovery Environment

Certain aspects of the posttrauma recovery environment may either contribute to the development and persistent of symptoms of PTSD, or may help to alleviate or mitigate such symptoms. Intervening life events/stressors and re-exposure to the traumatic event have been linked with greater persistence of PTSD and its symptoms among children and adolescents. In addition, parents' psychosocial functioning, including their levels of psychopathology and their own reactions to the disaster, are likely to affect children's postdisaster functioning. For example, mothers' distress in the aftermath of Hurricane Hugo, which struck Charleston South Carolina in 1989, was associated with the persistence of their children's postdisaster emotional difficulties. Other research has supported a linkage between children's symptoms

of PTSD and parents' trauma-related symptoms. Finally, children with more negative coping strategies for dealing with stress (e.g., anger or blaming others) show greater persistence in their symptoms of PTSD over time.

In contrast, the availability of social support has been found to mitigate the impact of trauma on children. Following traumatic events, such as severe abuse or catastrophic disasters, children with higher levels of social support from significant others (parents, teachers, friends, and classmates) report fewer symptoms of PTSD than those with low levels of social support. Because of these findings, efforts to enhance the social support of children exposed to trauma, and to encourage adaptive coping skills, may be useful for strategies for interventions with children following traumatic events.

Assessing Posttraumatic Stress Disorder Symptoms in Children

Evaluating the presence of PTSD symptoms in children and adolescents can be challenging and will depend, to some extent, on the age or developmental level of the child. For children of elementary school age and older (i.e., 7 years and above), the child or adolescent is likely to be the best informant; parents often underestimate symptoms of PTSD in their children.

The use of child-oriented structured interviews that contain items pertinent to the PTSD diagnosis, such as the Anxiety Disorders Interview Schedule for Children or the Diagnostic Interview Schedule for Children represent the most desirable way to assess such reactions. For screening purposes, when a large number of children are being evaluated, or when personnel constraints preclude the use of individual interviews, child-oriented self-report measures, such as the PTSD Reaction Index, have been found to be extremely useful.

Assessing symptoms of PTSD in children of pre-school age and younger typically requires the input of the parent or primary carer. Parent-versions of structured interviews would be the desired format to use, or parent-competed questionnaires reporting on children's PTSD symptoms. For young children, behavioral observations can be especially important in evaluating their reactions. Behaviors to evaluate include signs of distress, arousal, or fear, and behavioral avoidance of trauma-related objects, events, or situations.

Diagnostic Systems and Delayed Posttraumatic Stress
Disorder

Nature of the Delay Period

Discussing Delayed Posttraumatic Stress Disorder

Glossary

<i>Delayed posttraumatic stress disorder (D-PTSD)</i>	Posttraumatic stress disorder when the onset of symptoms occurs at least 6 months after the stressor.
<i>Stressor</i>	A traumatic event that gives rise to major stress responses.

Diagnostic Systems and Delayed Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) can be found in both the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (DSM-IV) of the American Psychiatric Association and the *International Classification of Diseases* (ICD-10) of the World Health Organization. The stressor criterion and the three symptom cluster criteria (intrusion, avoidance, and psychophysiological arousal), as well as the time frames, are fairly similar, though some differences exist.

In DSM-III through DSM-IV, PTSD is subsumed under anxiety disorders. When the disorder lasts at least 1 month and persists for less than 3 months after the stressful event, PTSD is considered acute. If the duration is more than 3 months, then PTSD is regarded as chronic.

In ICD-10, PTSD is placed under the heading F43, "Reaction to severe stress and adjustment disorders." The ICD-10 defines "Post-traumatic stress disorder" (F43.1) when the diagnostic criteria are met within 6 months of a major stressful event or of a period of stress. The ICD-10 gives yet another option: when patients have a chronic course, which involves major and lasting personality changes, the diagnosis of "Enduring personality changes, not attributable to brain damage and disease" (F62) may be used.

So far, there has been limited research into long-term personality changes.

Both DSM-IV and ICD-10 concur that delayed PTSD (D-PTSD) is diagnosed when at least 6 months have passed between the exposure of a major stressor and the full onset of PTSD.

Nature of the Delay Period

D-PTSD occurs when a person is reasonably well adapted for the initial 6 months or more after experiencing a major stressor but develops PTSD symptoms, such as intrusion, avoidance, and increased arousal related to the initial event, at some later stage. None of the diagnostic systems, however, characterize the nature of the delay period. Still, there is a limited body of research available to shed light on the subject. North et al., in a study published in 1997, found no cases of delayed-onset PTSD in 136 survivors 1 year after a mass shooting incident. Considerable discrepancy of identified PTSD cases was apparent between index and follow-up. The authors argued that inconsistency in reporting rather than true delayed onset was responsible for PTSD cases identified 1 year after the trauma. After the Oklahoma City bombing, survivors were studied 6 and 17 months postdisaster by the same author. Again, no delayed-onset cases were verified. At a 5-year follow-up, Holen found only one case of D-PTSD in the 72 survivors from the North Sea oil rig disaster.

A prospective study by Bryant et al. of 103 motor vehicle accident survivors studied within 1 month of the stressor and again at 6 months and 2 years post-accident identified five patients with PTSD at 2 years; they had not met the PTSD criteria at 6 months. Additionally, the authors reported that delayed-onset cases suffered subsyndromal levels of PTSD, with elevated resting heart rate levels prior to diagnosis. Buckley et al. also found delayed-onset survivors from motor vehicle accidents to be more symptomatic initially than those who did not develop PTSD. In addition, the delayed-onset survivors tended to have poorer social support systems than controls both prior to and after the stressor. Furthermore, the delayed-onset survivors had lower global assessment of function (GAF) scores than controls in the month prior to the motor vehicle accident. Schnurr et al. found that women were more likely to be in the delayed-onset cluster. In a prospective study of traffic accident victims by Koren et al., only 2 of 39 survivors without PTSD at 1 year posttrauma demonstrated delayed-onset PTSD 4 years later. In discussing

compensation issues, Eitinger and Holen argued that bridge symptoms, i.e., subclinical symptoms that persist from the time of the trauma to the manifestations of full-blown PTSD, may serve as precursors to delayed responses. In follow-up studies of the population from the collapse of the Buffalo Creek dam, Green et al. reported that 11% of the cases not identified with PTSD in 1974 met the criteria in 1986.

In a study published in 1989, Solomon et al. reviewed 150 randomly selected files of veterans who sought treatment for combat-related disorders; all the veterans were from the 1982 Lebanon war. Four reasons were given for why they asked for health services. In 10% of the sample, the delayed-onset PTSD was preceded by an initial asymptomatic period. After the war, some other veterans uninterruptedly suffered mild PTSD-associated symptoms until accumulated tension or exposure to subsequent adversity, either military or civilian in nature, resulted in full-blown PTSD. Such exacerbations of PTSD were seen in 33% of the veterans. Reactivation of an earlier combat stress reaction was found in 13% of the cases. The reactivation started only after an asymptomatic period and in connection with threatening military stimuli. Some veterans had no single trigger; they seemed to build up tensions over time with various exposures. Finally, one group of veterans was characterized by delayed treatment seeking for chronic PTSD; this accounted for as much as 40% of the cases. In the absence of proper definitions, the first three groups, i.e., those with an initial asymptomatic period, those with exacerbations, and those with reactivated responses, may qualify as varieties of D-PTSD or they may represent different kinds of posttraumatic processing. The veterans from the 1982 Lebanon war with delayed-onset PTSD used significantly more emotion-focused and distraction coping on the Ways of Coping Checklist than control subjects. Furthermore, they used coping skills significantly less than those with immediate-onset PTSD.

From 1968 to 1973, decades before PTSD was invented, Eitinger and Stroem studied the health of Norwegian concentration camp survivors. They reported a high occurrence of late-onset somatic and psychiatric manifestations associated with concentration camp syndrome, or the KZ syndrome.

In a study of aging Resistance veterans from Holland, Aarts et al. found that the period between the end of the war and when the first symptoms of PTSD appeared varied considerably. First onset of PTSD symptoms appeared in 26% of the cases during the first 5 years after World War II. However, in about 50% of the veterans, PTSD manifested after more than 20 years.

Discussing Delayed Posttraumatic Stress Disorder

There are many uncertainties and controversies in the current conceptualizations of D-PTSD. Some authors report no cases of D-PTSD and raise doubts about the legitimacy of the concept. Others bring up the question of whether D-PTSD represents a latent disorder or simply is unrecognized PTSD. In recent years, a growing number of studies involving both motor vehicle accidents and combat-related stressors have demonstrated occurrence rates of D-PTSD around 10% when manifestation of the disorder is preceded by an asymptomatic period. Moreover, several studies point toward vulnerability factors in both the survivors and their environments. Persons who tend to have subsyndromal symptom levels in the delay period are more likely to have poorer social networks, poorer coping skills, and lower GAF scores.

Some researchers, such as Horowitz, argue that posttraumatic symptoms may wax and wane with triggers or life events. According to the diagnostic criteria of PTSD in the DSM-IV, the triggers are internal or external cues that symbolize or resemble aspects of the primary stressor. When a person is exposed to triggers, his or her state may change from asymptomatic or subthreshold to symptomatic, or from prodromal mild to severe, and thus meet the diagnostic criteria of D-PTSD. Most researchers and clinicians would probably regard triggers as idiosyncratic, low-grade events with no or only a minimal impact on most people, which, in contrast, lead to major responses in survivors. On the contrary, events leading to reactivation may be regarded as having more impact and being traumatic in a general sense. The notion of reactivation implies that past traumas lower the threshold for certain stressors that may symbolize or resemble the primary stressor, and entail far stronger responses than would be seen in most people. The boundaries between episodes of reactivation as part of D-PTSD and episodes of a new PTSD are rather blurred.

In discussing D-PTSD and concepts such as triggers, reactivating events, and primary stressors, the need for clearer definitions becomes quite apparent. Furthermore, gradients and/or classifications of events may be relevant. More studies are needed to shed light on these issues as well as on the course of the posttraumatic processing. What roles do the primary stressor, the subsequent triggers and aversive events, personality, and the social environment play when full-blown PTSD occurs after a completely asymptomatic period, or after a time dominated by subthreshold levels of PTSD symptoms? If the subthreshold symptoms affect the life of the person to a maladaptive degree yet do not meet the criteria of

PTSD, the person might within certain time limits be diagnosed as having an adjustment disorder.

Many central questions regarding D-PTSD are still unanswered. We do not know much about possible links to aging. More research is needed to expand our current knowledge about the vicissitudes of delayed posttraumatic stress.

Posttraumatic Stress Disorder: Biology and Phenomenology
Animal Models for Posttraumatic Stress Disorder
Neurotransmitter and Neuropeptide Systems Involved in Stress and Posttraumatic Stress Disorder

Effects of Stress on the Neurobiology of Learning and Memory
Concluding Remarks

Glossary

<i>Amygdala</i>	A small, walnut-shaped brain area in the center of the brain, involved in fear responses.
<i>Cortisol</i>	The stress hormone in humans (glucocorticoid is a more general term, referring to the stress hormone in all animal species).
<i>Extinction</i>	The inhibition of fear responses; felt to be mediated by the medial prefrontal cortex.

<i>Hippocampus</i>	The subcortical brain area involved in learning and memory.
<i>Medial prefrontal cortex</i>	Part of the frontal cortex (brain area just above the eyes) that is involved in emotion and social behaviors; may be involved in posttraumatic stress disorder symptoms.
<i>Magnetic resonance imaging</i>	An imaging technique that can provide detailed maps of brain structure as well as function.
<i>Norepinephrine</i>	A stress neurotransmitter that mediates fight-or-flight responses.
<i>Positron emission tomography (PET)</i>	An imaging technique that uses radiolabeled substances to provide information about brain function.
<i>Posttraumatic stress disorder (PTSD)</i>	A psychiatric disorder, listed in the <i>Diagnostic and Statistical Manual of Psychiatry</i> , that follows exposure to an extreme stress that was a threat to life; it is accompanied by intrusive thoughts, startle, sleep disturbance, hyperarousal, and other symptoms.

Posttraumatic Stress Disorder: Biology and Phenomenology

PTSD affects 8% of people at some time during their lives. PTSD is characterized by specific symptoms,

including intrusive thoughts, hyperarousal, flashbacks, nightmares, sleep disturbance, changes in memory and concentration, and startle responses, that develop following exposure to extreme stress. The symptoms of PTSD are a behavioral manifestation of stress-induced changes in brain structure and function. Stress results in acute and chronic changes in neurochemical systems and specific brain regions, which result in long-term changes in the brain circuits involved in the stress response. Brain regions felt to play an important role in PTSD include the hippocampus, amygdala, and medial prefrontal cortex. Cortisol and norepinephrine are two neurochemical systems that are critical in the stress response. When we refer to the neurobiology of PTSD, we are referring to the aggregate of these stress-induced changes in the brain (Figure 1).

Animal Models for Posttraumatic Stress Disorder

Animal models of stress have been used in the study of stress-related psychiatric disorders, including PTSD. Animals exposed to repeated stress from which they cannot escape develop specific fear-related behaviors that are associated with lasting changes in stress-related neurochemical systems. Behavioral changes related to stress include weight loss and decreases in food intake, active behavior in novel environments,

Figure 1 A model for the neurobiology of PTSD. Stress has an effect on multiple brain areas that are responsible for mediating the stress response. These include the amygdala, hippocampus, medial and orbitofrontal cortex, cerebral cortex, hypothalamus, and brain stem. These regions are functionally interrelated and represent important substrates for neurochemical systems involved in the stress response. Long-term changes in the function and structure of these regions lead to symptoms of PTSD. ACTH, adrenocorticotropic hormone; BP, blood pressure; BZ, benzodiazepine; CRH, corticotropin-releasing hormone; DA, dopamine; GC, glucocorticoid; HR, heart rate; NE, norepinephrine.

competitiveness and normal aggressiveness, grooming, play activity, responding for rewards, and self-stimulation of brain reward centers, as well as deficits in memory and attention, sleep disturbances, and increased defecation. These behaviors are similar to stress-related behaviors seen in patients with PTSD.

Neurotransmitter and Neuropeptide Systems Involved in Stress and Posttraumatic Stress Disorder

The locus coeruleus-noradrenergic system plays an important role in the stress response. The majority of norepinephrine cell bodies in the brain are located in a brain-stem site called the locus coeruleus (dorsal pons), with long neurons that project to multiple cortical and subcortical brain sites (e.g., the hippocampus, amygdala, and hypothalamus) for the direct release of the norepinephrine neurotransmitter. A variety of stressors result in an increase in locus coeruleus firing, with increased norepinephrine release in the brain and increased stress-related behaviors (e.g., increased vigilance and fight or flight) that are adaptive in survival. Animals with a history of chronic stress show a potentiated norepinephrine response with reexposure to subsequent stressors. The sensitization of noradrenergic responses may partially underlie the clinical phenomenon of stress sensitization seen in PTSD (e.g., childhood abuse increased the risk of PTSD in veterans who served in Vietnam).

A variety of studies showed long-term dysregulation of the noradrenergic system in PTSD. Kardiner noted in 1941 that veterans with psychiatric conditions related to their war experiences exhibited what appeared to be a hyperresponsiveness of the sympathetic system, manifested by increases in heart rate, blood pressure, sweatiness, irritability, palpitations, vertigo, dizziness, nausea, and syncope. Psychophysiology studies demonstrated an increase in sympathetic responses (heart rate, blood pressure, and galvanic skin response) to traumatic reminders, such as traumatic slides and sounds or traumatic scripts, in PTSD. An increase in norepinephrine and epinephrine was found in 24-h urine samples of patients with combat-related PTSD in some studies but not in others. Plasma levels of norepinephrine were not elevated at baseline in PTSD; however, a potentiated release of norepinephrine was found following exposure to traumatic reminders. Studies of peripheral adrenergic platelets (used as a marker of circulating levels of norepinephrine and epinephrine) have had mixed results. The administration of the adrenergic antagonist yohimbine, which results in an increase in the release of norepinephrine in the brain, resulted in an increase in PTSD-specific

symptomatology, as well as a greater release of norepinephrine metabolites in plasma in PTSD patients. Alterations in central metabolic responses to yohimbine were also found in PTSD patients as measured with PET. Yohimbine was associated with a differential effect on brain metabolism in neocortical areas, including the orbitofrontal, temporal, prefrontal, and parietal cortex, with metabolism having a tendency to increase in the controls and decrease in the patients. Given the dose-response effects of norepinephrine on cortical metabolism, these findings are consistent with a potentiated release of norepinephrine in PTSD. In summary, studies are consistent with an increased responsiveness of the norepinephrine system in PTSD.

The mesocortical dopaminergic system, which involves projections from the midbrain to the medial prefrontal cortex, is the most sensitive neural system to mild stressors. Both acute and chronic stressors result in a selective increase in dopamine release and metabolism in the medial prefrontal cortex. The few studies performed in PTSD showed elevations of dopamine and its metabolites in 24-h urine samples. Future work is needed in this important area.

The corticotropin-releasing hormone (CRH)-hypothalamic-pituitary-adrenal (HPA) axis system plays an important role in the stress response. Exposure to stressful situations is associated with a marked increase in cortisol release from the adrenal. Glucocorticoids are important in affecting many of the expressions of the stress response, such as increased gluconeogenesis, inhibition of growth and reproductive systems, and containment of inflammatory responses. Glucocorticoid release from the adrenal is regulated by adrenocorticotrophic hormone (ACTH) release from the pituitary, which in turn is regulated primarily by CRH release from the paraventricular nucleus (PVN) of the hypothalamus. In addition to the PVN, CRH is distributed in several brain areas that have been implicated in the behavioral and physiological responses to stress, including the central nucleus of the amygdala, hippocampus, prefrontal and cingulate cortices, locus coeruleus, thalamus, periaqueductal gray, and cerebellum. Intraventricular injection of CRH results in stress-related behaviors (e.g., fearfulness). Stressors early in life may have long-term effects on the CRH-HPA axis, including an increased glucocorticoid response to subsequent stressors. Glucocorticoids have profound effects on neuronal development, which means that early stressors could have lasting effects on development of the brain.

Studies in human subjects have validated the important role of glucocorticoids (cortisol in the human) for the stress response. Stress results in an acute increase in cortisol release, with psychological factors (such as

personal coping, appraisal, and previous stress exposure) modulating cortisol responsiveness. Long-term dysregulation of the HPA axis is associated with PTSD. Baseline levels of urinary cortisol were either decreased or unchanged in chronic PTSD, whereas decreased levels were found in 24-h samples of plasma cortisol levels. Cortisol may be elevated in the more acute phase of PTSD, although further research is needed in this area. A replicated finding has been a suppression of the cortisol response after lower doses of dexamethasone suppression test (DST) (0.5 mg), a finding that is the opposite of patients with major depression, who are nonsuppressors with the standard 1-mg DST test. PTSD patients had elevated levels of CRH in the cerebrospinal fluid. Other studies showed an increase in lymphocyte glucocorticoid receptors in PTSD and enhanced cortisol response to stress. One possible explanation of findings to date is an increase in neuronal CRH release, increased central glucocorticoid receptor responsiveness, and resultant low levels of peripheral cortisol due to enhanced negative feedback.

Other neurochemical systems may play a role in symptoms of PTSD. Benzodiazepinelike substances occur naturally in the brain and have been hypothesized to play a role in anxiety and stress. Animal models showed decreased benzodiazepine binding in the frontal cortex with acute and chronic stressors. Consistent with this, neuroimaging studies involving the quantitation of benzodiazepine receptor binding in the human brain showed decreased binding in frontal cortex of patients with PTSD. No difference was found in the anxiety response to the benzodiazepine receptor antagonist flumazenil between patients with combat-related PTSD and controls. Exposure to stress results in an increased release of opiate peptides in the brain associated with the development of an analgesia to pain known as stress-induced analgesia. Opiates cause a decrease in firing from the locus coeruleus; this provides an explanation for the favorable response of hyperarousal symptoms of PTSD to opiates such as heroin. Vietnam veterans with PTSD had a reduced sensitivity to pain during exposure to traumatic reminders in the form of a videotape with combat-related scenes; this was reversible with the opiate antagonist naloxone. Studies showed decreased levels of β -endorphin in the cerebrospinal fluid of patients with PTSD. Stressors result in increased serotonin (5-HT) turnover in the medial prefrontal cortex. Chronic restraint stress results in a decrease in 5-HT_{1A} binding in the hippocampus and in a decrease in 5-HT₂ binding in the parietal cortex. Patients with combat-related PTSD had reduced paroxetine-binding sites in platelets (evidence of reduced serotonin reuptake site function). Other studies found no difference in platelet

serotonin levels or uptake or in response to probes of 5-HT_{1A} function. Thyroid hormone (thyroxine, T₃) was found to be increased, with a pattern of increased thyrotropin-stimulating hormone response to thyrotropin-releasing hormone in PTSD. Other studies showed increased somatostatin levels in cerebrospinal fluid and decreased levels of neuropeptide Y (NPY) in plasma in PTSD.

Effects of Stress on the Neurobiology of Learning and Memory

There has been considerable interest in alterations in memory function in PTSD. Memory alterations in PTSD take the form of deficits in explicit verbal memory as well as in potentiation of recall of traumatic experiences, dissociative flashbacks, and changes in implicit memory (e.g., fear conditioning). Brain areas, including the hippocampus, amygdala, and medial prefrontal cortex, may mediate these alterations in memory. The hippocampus, a brain area involved in verbal declarative memory, is very sensitive to the effects of stress. Stress in animals was associated with damage to neurons in the CA3 region of the hippocampus with associated deficits in learning and memory. Studies in a variety of animal species suggested that direct glucocorticoid exposure results in decreased dendritic branching and a loss of neurons in the hippocampus. Glucocorticoids appear to exert their effect by increasing the vulnerability of hippocampal neurons to insults such as excitatory amino acids. Other factors, including alterations in serotonin function and decreased levels of brain-derived neurotrophic factor, also probably contribute to stress-related hippocampal damage. Recently, stress has been shown to inhibit neurogenesis, an effect that is reversed by antidepressant treatment.

Studies in PTSD are consistent with abnormalities of the hippocampus. PTSD patients show specific deficits in verbal declarative memory function based on measures that have been validated as sensitive to the loss of neurons in the CA3 region of the hippocampus. Patients with PTSD secondary to combat or childhood abuse also had a smaller volume of the hippocampus based on measurements with magnetic resonance imaging. Deficits in memory were correlated with reduced hippocampal volume in patients with combat-related PTSD. Declarative memory function improved and hippocampal volume increased with antidepressant treatments, including paroxetine and phenytoin. We have hypothesized that stress-induced hippocampal dysfunction may mediate many of the symptoms of PTSD that are related to memory dysregulation, including explicit memory deficits and

fragmentation of memory in abuse survivors. The hippocampus and adjacent cortex plays an important role in binding together information from multiple sensory cortices into a single memory at the time of retrieval. Abnormalities of hippocampal function in PTSD may impair the ability of the hippocampus to recreate a normal memory. Traumatic memories may not be placeable in space and time, leading to fragmentation or amnesia. Traumatic memories may intrude into consciousness without any discernible reason, leading to the symptom of intrusive memories and flashbacks.

The amygdala is involved in memory for the emotional valence of events. The paradigm of conditioned fear has been used as an animal model for stress-induced abnormalities of emotional memory. When an aversive stimulus (e.g., electric shock) is paired repeatedly with a neutral stimulus (bright light), exposure to the conditioned stimulus alone results in an increase in fear responsiveness and an increased startle response. This phenomenon, known as fear conditioning, is mediated by the amygdala. The startle response has been used as a probe of amygdala function in humans. In PTSD patients, the startle response has been shown to be either equal to or greater than that seen in normal subjects. Imaging studies have shown increased amygdala response to external threats, such as fear conditioning or exposure to fearful faces, but not during exposure to internally generated traumatic reminders.

The medial prefrontal cortex has been hypothesized to mediate symptoms of PTSD. The medial prefrontal cortex includes the anterior cingulate gyrus (Brodmann's area 32) and subcallosal gyms (area 25), as well as orbitofrontal cortex, and is functionally and anatomically distinct from the dorsolateral prefrontal cortex. Lesion studies demonstrated that the medial prefrontal cortex is involved in emotion and social behavior. Medial prefrontal cortical areas modulate emotional responsiveness through the inhibition of amygdala function, and dysfunction in these regions may underlie pathological emotional responses in patients with PTSD. Conditioned fear responses are extinguished following repeated exposure to the conditioned stimulus in the absence of the unconditioned (aversive, e.g., electric shock) stimulus. The extinguished memory is rapidly reversible following reexposure to the conditioned-unconditioned stimulus pairing even up to 1 year after the original period of fear conditioning, suggesting that the fear response did not disappear but was merely inhibited. This inhibition appears to be mediated by the medial prefrontal cortical inhibition of amygdala responsiveness. Studies in animals showed that early stress results in decreased brain neurons in the medial prefrontal cortex. Imaging studies in PTSD show a smaller volume of the anterior

cingulate. Imaging studies of brain function in PTSD are consistent with dysfunction of the medial prefrontal cortex during the presentation of traumatic cues. Stimulation of PTSD symptoms with the noradrenergic agent yohimbine resulted in a relative failure of activation of metabolism in parts of the medial prefrontal cortex, as well as decreased function in the hippocampus, as measured with the PET assessment of metabolism in PTSD. Exposure to traumatic reminders in the form of traumatic slides and sounds or traumatic scripts was associated with an increase in PTSD symptoms, decreased blood flow in the medial prefrontal cortex and anterior cingulate, and a failure of activation in the anterior cingulate (areas 32 and 24), as measured with PET. Traumatic reminders also resulted in increased activation in the posterior cingulate and motor cortex in two or more studies in PTSD. These areas are involved in visuospatial processing and preparation for action that may be critical to the fight-or-flight response. A decreased function in the hippocampus was also seen in two studies. In summary, dysfunction of the medial prefrontal cortex during exposure to traumatic reminders may underlie the symptoms of PTSD.

Concluding Remarks

Multiple neurotransmitter and neuropeptide systems are involved in the stress response, including CRH, norepinephrine, serotonin, dopamine, endogenous benzodiazepines, and endogenous opiates. These transmitters mutually regulate one another in the execution of the stress response. Chronic stress is associated with long-term alterations in these transmitters and peptides, which translate into changes in neuronal function and structure. Preliminary clinical studies in patients with PTSD are beginning to replicate many of the findings from animal studies. Specific brain regions, including the hippocampus and adjacent cortex, amygdala, and medial prefrontal cortex, are hypothesized to play a role in symptoms of PTSD. Neurotransmitter and neuropeptid systems involved in stress modulate behavior and memory function through direct actions on these brain regions. Chronic stress, probably through long-term alterations in these systems, can lead to long-term behavioral and memory disturbances. This may represent the mechanism for many of the symptoms of PTSD.

Stress Disorder (PTSD) and Acute Stress Disorder (ASD)

Early Interventions

Treatment of PTSD

The Pharmacological Treatment of PTSD

Summary

Glossary

*Double-blind
study*

A research study in which both the research patient and the research clinician are blind or unaware of the type of medication or other intervention being used to treat the patient. This prevents the expectations of the patient and researcher

from biasing the research results. In such studies, a research pharmacist or another medical clinician not in direct contact with the patient knows which medication the patient is taking so that appropriate steps can be taken if the patient develops any side effects.

Extinction

The process of learning that a stimulus strongly paired with a traumatic event (e.g., gunshots) is no longer associated with the traumatic event (e.g., combat). This process requires that the person be re-exposed to trauma-related stimuli, and can cause high levels of distress. However, as the person learns that the traumatic event is no longer going to occur in association with that stimulus, anxiety, fear, defensive, and avoidance behaviors subside.

Flashback

Acting or feeling like one is re-experiencing a traumatic event after it is over. A flashback may seem to occur spontaneously or may occur in response to a sight, sound, smell, or other sensation associated with the initial trauma (e.g., in response to hearing a car backfire, seeing a person that resembles the perpetrator of an assault, feeling the ground vibrate, smelling fire). The person experiencing the flashback may retain a partial

Neuro-transmitter

awareness of reality or completely lose touch with reality.

A chemical released by neurons (nerve cells) in the brain or peripheral nervous system to communicate with other neurons. Neurotransmitters interact with receptors on nearby neurons, or on the neuron from which the neurotransmitters were released, to increase or decrease their activity. Medications used to treat PTSD are known to influence levels or efficacy of the following neurotransmitters or neurotransmitter receptors: serotonin, norepinephrine (noradrenalin), epinephrine (adrenaline), acetylcholine, dopamine, and γ -aminobutyric acid (GABA).

Placebo

An inactive pill given to persons participating in research studies to examine the effectiveness of new medications. Some psychiatric symptoms can improve in response to a placebo substance because individuals getting that substance think that the new medication will be helpful. This is called a placebo response. The symptom responses of persons getting a placebo medication are then compared to the responses of persons getting the real medication. Since real medications usually have some undesirable side effects, a real medication must be able to improve symptoms more than a placebo in order for the real medication to be considered effective and worthwhile.

Background: Diagnosis and Symptoms of Posttraumatic Stress Disorder (PTSD) and Acute Stress Disorder (ASD)

Diagnosis of PTSD

Posttraumatic stress disorder (PTSD) is diagnosed when criteria A, B, C, and D set forth in the *Diagnostic and Statistical Manual of Mental Disorders*, fourth edition, text revision (DSM-IV-TR) are met.

To meet criterion A, a person must have experienced or witnessed, or have been confronted with, an event perceived as extremely threatening (criterion A1) in association with an intense feeling of helplessness, horror, or fear (criterion A2). Examples of traumatic events include being physically assaulted, being raped, participating in combat, being a victim of a natural disaster such as an earthquake or tornado, being in a car accident, witnessing a murder, or hearing about the sudden and unexpected homicide of a loved one. Symptoms of PTSD that may develop

in response to a traumatic event comprise the B, C, and D criteria. At least one re-experiencing symptom (criterion B), three avoidance symptoms (criterion C), two hyperarousal symptoms (criterion D), and evidence of functional impairment must be present for a diagnosis of PTSD to be made.

Symptoms of PTSD

Re-experiencing symptoms Re-experiencing symptoms of PTSD include bothersome intrusive memories, thoughts, or images of the trauma, nightmares, flashbacks, and emotional or physiological reactions to stimuli associated with the initial trauma.

Avoidance/numbing symptoms Avoidance/numbing symptoms of PTSD include going out of one's way to avoid stimuli associated with the trauma (e.g., not driving after a car accident, avoiding 4th of July fireworks celebrations after experiencing combat trauma, using alcohol or other drugs of abuse to avoid feelings or memories of the trauma), not discussing the traumatic event because of feelings that get stirred up, partial or complete amnesia for the event, disinterest in everyday activities, emotional numbing, and the sense that one's future is dismal or will be cut short.

Hyperarousal symptoms Hyperarousal symptoms of PTSD include hypervigilance, irritability, anger or rage, difficulty concentrating, startle reactions, and sleep disturbances. The latter may include difficulty falling asleep, middle of the night awakening (often in reaction to nightmares), and early morning awakening. It is not uncommon for persons with untreated PTSD to regularly obtain less than 6 h of sleep per night.

Time Course Depending on the duration of PTSD symptoms and the onset of PTSD symptoms relative to the experience of trauma, three PTSD subtypes may be diagnosed. Treatment approaches may vary depending on the timing and course of symptoms. Acute PTSD is diagnosed when symptoms of PTSD remain or develop more than 1 month after the trauma. Symptoms of acute PTSD may last up to 3 months in duration. Chronic PTSD is diagnosed when PTSD symptoms last longer than 3 months, and delayed-onset PTSD is diagnosed when PTSD symptoms develop more than 6 months after the trauma.

Diagnosis of ASD

A diagnosis of acute stress disorder (ASD) requires the presence of at least three symptoms of dissociation (subjective numbing, detachment, or an absence

of emotional responsiveness, an unawareness of surroundings, derealization, depersonalization, or dissociative amnesia), along with one re-experiencing, one hyperarousal, and one avoidance symptom (discussed previously). By definition, these symptoms may last up to 4 weeks from the trauma. The development of ASD predicts the development of PTSD, though not all persons that develop ASD go on to develop PTSD, and not all persons that develop PTSD have experienced a readily diagnosable ASD.

Comorbid Disorders Associated with PTSD

Other psychiatric disorders such as depression, panic disorder, substance abuse, somatization disorder, phobias, and dissociative disorders are commonly associated with PTSD. It is thought that depression and panic disorder when associated with PTSD are neurobiologically distinct from these disorders diagnosed in the absence of trauma exposure. Alcohol, nicotine, or drug abuse may constitute attempts by the patient to maladaptively cope with PTSD symptoms. Thus, the presence of a substance use disorder in a person suffering from PTSD can, in many cases, be construed as an avoidance symptom that has significant secondary adverse effects on the person's adaptation. It is also possible that individuals with comorbid PTSD and substance use disorders have risk factors that predispose them to both. Interestingly, the risk for nicotine dependence is increased by having PTSD, while the risk for the development of PTSD, after trauma exposure, is increased by prior nicotine dependence. Chronic pain and stress-exacerbated medical disorders such as gastric ulcers or irritable bowel syndrome also occur frequently in persons with PTSD. The presence of these comorbid psychiatric and medical disorders can significantly complicate the treatment of PTSD (see later).

Trauma exposure can lead to an intensification of central neurochemical and peripheral neurohormonal responses to perceived threat. Associated state changes facilitate fight or flight reactions at the expense of higher-order cognitive efforts to appraise the actual degree of threat and enact appropriate, considered responses. Patients with PTSD therefore often have problems with impulse control and defensive aggression. Traumatic experiences in childhood and even early adulthood often lead to the development of affect dysregulation, cognitive misappraisals, interpersonal problems, and behaviors that cause self-harm. These symptoms are sometimes considered features of borderline, narcissistic, and antisocial personality disorders, while others consider them symptoms of complex PTSD. Trauma experienced during adulthood

may sometimes precipitate the emergence of similar problems along with the development of PTSD even in previously well-functioning individuals. Therapists engaging in the treatment of PTSD therefore should have familiarity with, comfort with, and experience in the management of these defensive, maladaptive patterns of function in order to maintain a therapeutic relationship within which treatment can proceed.

Early Interventions

The risk for developing PTSD after exposure to a traumatic event depends on the type and severity of the trauma, as well as the age, gender, and other premorbid characteristics of the person suffering the trauma. For example, PTSD is thought to occur at higher rates in response to unpredictable or uncontrollable events and in response to interpersonal trauma resulting from the breakdown of expectable psychosocial norms (e.g., rape, genocide, war atrocities, intrafamilial abuse). Research also suggests that a history of childhood trauma may predispose to the development of PTSD in response to adult trauma. Genetic factors may also predispose to the development of PTSD. Finally, the degree of psychosocial support experienced in the aftermath of trauma affects the progression of ASD to PTSD (see later).

Understanding the mechanisms by which the preceding factors contribute to the risk for PTSD will help lead to new methods of PTSD prevention. In the meantime, significant progress has been made in evaluating the efficacy of early interventions aimed at preventing the progression of acute trauma reactions to PTSD. Single-session debriefing therapy was the first such treatment widely employed. During debriefing therapy, trauma victims are educated about typical stress reactions and ways to cope with them. Victims are also encouraged to express feelings and thoughts about the trauma and are informed about other treatments that may be accessed later should the need arise. Controlled trials of debriefing therapy, however, have not only failed to show its efficacy, but also suggest that it might increase the risk for PTSD. Since these studies, research methodologists have emphasized the importance of comparing outcomes of experimental therapies to the natural evolution of trauma symptoms.

Much better outcomes have been found with cognitive-behavioral therapies that employ exposure techniques and/or cognitive restructuring interventions. These interventions have been introduced a few months after trauma exposure and are significantly more effective in preventing PTSD than supportive psychotherapies, the simple repetition of PTSD

symptom assessments, and self-help programs. Importantly, rates of PTSD remittance in response to early cognitive-behavioral interventions are also much higher than natural rates of PTSD remission.

Further research is needed to determine whether even earlier psychological or pharmacological interventions may protect against the development of PTSD, as suggested by preliminary controlled studies of short-term propranolol administration to trauma victims seen initially in an emergency room setting.

Treatment of PTSD

Exposure Therapy

Exposure therapies used to treat PTSD are derived from research into the mechanisms underlying classical and operant conditioning. For instance, it has been fairly well established that traumatic memories are indelibly encoded within the amygdala, a part of the brain that coordinates the hormonal, cardiovascular, behavioral, and cognitive responses to threat in mammals. Within the amygdala, memories of the naturally threatening (i.e., unconditioned) stimulus and the initially nonthreatening stimuli associated with the threatening stimulus become paired at a neuronal level, so that in the future, the previously neutral but now fear-conditioned stimuli alone can elicit fearful defensive responses. Over time, if the individual repeatedly reencounters conditioned stimuli in the absence of the original threatening stimulus, new information about the safety of the conditioned stimuli restrains activation of the amygdala, and the expression of conditioned fear eventually extinguishes. Indeed, it is believed that the success of exposure therapy in PTSD relies in large part on the engagement and enhancement of this natural extinction process.

There are several types of exposure therapy used in the treatment of PTSD. These treatments vary in three ways: (1) the exposure to trauma-related stimuli may be imaginal or involve actual confrontation with feared persons, places, or things; (2) the exposure may be short or long; and (3) the level of emotional arousal stimulated by the exposure may be low or high. In systematic desensitization, patients are instructed to relax, and then are asked to imagine a minimally threatening stimulus for a short period of time. This is repeated several times until the stimulus ceases to cause anxiety. The patient is then asked to imagine a more fearful stimulus for several repetitions until it ceases to elicit anxiety. This process continues until the most threatening situation can be comfortably confronted by the patient. In flooding, the patient starts by confronting the most highly

feared stimuli either in the imagination or *in vivo*. The exposure is prolonged and elicits very high levels of anxiety.

Perhaps the most rigorously studied type of exposure therapy is called prolonged exposure (PE). PE is typically conducted in 7 to 10 sessions and involves a combination of imaginal and *in vivo* exposure. After education regarding PTSD, rationale building, and breathing retraining, the therapist and client develop a hierarchy of feared situations for *in vivo* exposure practice between sessions. Then during sessions, which are 90 min in length, imaginal exposure is conducted in which the client is asked to relate the worst traumatic event, in present tense, including as many sensory details as possible. The account is repeated for 45 to 60 min during the session, which is audiotaped. The client listens to the tape between sessions until the next exposure session is taped.

In well-designed studies, PE has been found to result in remission of PTSD in approximately 50% of patients treated. Further studies have suggested that the degree of arousal experienced during exposure therapy influences its outcome. Thus, future research will be needed to identify factors that interfere with achievement of optimal levels of arousal necessary for extinction to occur. Interventions then could be developed to mitigate the impact of such factors. For example, Foa and Meadows have described several anxiety management techniques that could be used by patients with PTSD to manage disabling levels of anxiety induced by exposure to trauma-related cues. Other techniques may help patients who willfully or automatically avoid experiencing necessary levels of arousal and distress during exposure therapy. For patients with neurobiologically mediated tendencies toward over- or underarousal, medications might be used in combination with exposure techniques.

Cognitive Therapy

Cognitive therapy aims to identify, challenge, and restructure automatic systems of meaning that have become attached to traumatic experiences and that interfere with the ability to accurately interpret current events. Cognitive theories of PTSD focus on the effect that various beliefs and schemas (automatic rules) have on emotions and how the memory of the traumatic event may be discrepant with a person's understanding of him- or herself and his or her world view. Cognitive therapy assists the client in examining beliefs about the traumatic event, his or her self, and the world and helps the client challenge possible erroneous and maladaptive assumptions. In several studies, cognitive therapy has been found to be as effective as exposure therapy.

Combination Strategies

Cognitive processing therapy (CPT) Cognitive processing therapy (CPT) utilizes a combination of exposure and cognitive therapy over the course of 12 1-h sessions. CPT was first shown to be efficacious in women with assault-related chronic PTSD, inducing remission of PTSD in about 50% of those who initiated treatment and 80% of those who completed treatment. Since then, CPT has been successfully extended to the treatment of male Vietnam veterans with chronic combat-related PTSD.

During the exposure component of CPT, the patient writes an account of his or her worst traumatic event, reads the account daily, and then reads it to the therapist in session. The patient is encouraged to experience the full range of emotions associated with that event. Most people with PTSD re-experience the traumatic event as only brief sensory images rather than the complete story. Writing the account in detail restores the full event within its greater context. In addition, reviewing the details of the traumatic experience allows the therapist and patient to consider possible assumptions that were made at the time of the trauma and distortions in the patient's retrospective evaluation of the traumatic event that have interfered with recovery. For example, victims of trauma often overestimate the amount of control they had over the event. Self-blame by patients is frequent even when it is obvious to everyone else that the event was not preventable. These cognitive distortions, believed to play a role in the maintenance of PTSD, are referred to as stuck points.

During the subsequent cognitive therapy sessions, patients are taught to systematically challenge their counterproductive thoughts by asking and answering a series of questions and then generating more balanced alternative thoughts. During CPT, new reality-based thoughts begin to supplant the conditioned and overgeneralized automatic beliefs, leading to a marked reduction in re-experiencing, avoidance, and hyperarousal symptoms. Systematically addressing deleterious effects of the traumatic experiences on the victim's self-concept and relationships with others also results in significant reductions in depression and guilt. Indeed, CPT has been found to be modestly more effective than prolonged exposure therapy in reducing depression. It is also more effective in reducing guilt and somatic symptoms comorbid with PTSD.

The therapeutic effects of these evidence-based cognitive-behavioral therapies can be profound and have been shown, in a long-term follow-up study, to persist up to 5 years after treatment.

Eye movement desensitization reprocessing (EMDR) During eye movement desensitization reprocessing

(EMDR), a patient tracks the movement of a therapist's finger, while visualizing a traumatic scene and paying attention to any thoughts or feelings provoked by the scene. The therapist takes note of whether the patient's appraisal of the circumstances or meaning of the trauma may be distorted and thereby contribute to negative feelings associated with the incident. This process is repeated until the anxiety generated by the traumatic scene subsides. At this point, the therapist interjects an alternate, and ideally more realistic or constructive, thought about the trauma scene for the patient to consider. This positive association is thought to compete with negative associations and contribute to the extinction of conditioned fear.

It is important to note that recent research has suggested that having the patient follow the movement of the therapist's finger may lessen the intensity of the emotional response to the visualized traumatic material. Thus, having the patient engage in other mildly distracting repetitive movements also may be useful in optimizing the degree of arousal attained during this imaginative exposure exercise and thus may facilitate extinction.

A recent study has found that prolonged exposure therapy results in greater improvements in PTSD symptoms than EMDR, while EMDR did not differ significantly in efficacy from relaxation therapy. A head-to-head comparison between CPT and EMDR has not been conducted.

Treatment of Complicated PTSD

As noted, the presence of comorbid medical and psychiatric conditions can significantly complicate the treatment of PTSD. Although it has been generally believed that substance use disorders need to be addressed before the treatment of PTSD, there have been recent efforts to treat comorbid substance abuse and PTSD simultaneously, with positive effects. States of intoxication as well as withdrawal intensify PTSD symptoms and may compromise the natural biological processes involved in extinction and the development of more reality-based cognitions. In addition, substance dependence results in secondary psychosocial problems (legal, vocational, interpersonal) that further stress and destabilize individuals struggling with PTSD. Comorbid depression also may complicate recovery from PTSD. While both PE and CPT have been shown to significantly decrease depressive symptoms in patients with PTSD, women with PTSD and comorbid major depression have significantly higher self-reported PTSD and depression symptoms at baseline and after treatment with CPT and PE compared to women with PTSD alone. Severe problems with affect regulation frequently

seen in victims of childhood abuse can also present a challenge during PTSD treatment. In addition, chronic pain syndromes associated with PTSD need to be addressed because chronic pain appears to increase PTSD symptoms and vice versa.

Therefore, treatments for PTSD in persons with comorbid psychiatric and medical conditions deserve attention in future research studies. For example, severe dysregulation of affect has been specifically targeted in one therapy format prior to undertaking prolonged exposure therapy in victims of childhood abuse. It has been suggested that comorbid major depression or panic disorder should be addressed pharmacologically prior to undertaking formal treatment of core PTSD symptoms. On the other hand, it is possible that substantial numbers of such patients may be refractory to antidepressants or other medications currently available (see later), or that therapeutic techniques as well as medication administration may be helpful. The treatment of chronic pain syndromes associated with PTSD can also be difficult. Standard pain medications such as nonsteroidal anti-inflammatory agents may be ineffective, while tolerance to more effective agents such as opiates can occur; in addition, the possibility that drugs such as opiates may interfere with exposure and cognitive techniques needs to be evaluated. Antidepressants may effectively treat both chronic pain and PTSD in some individuals, but do not benefit all.

The Pharmacological Treatment of PTSD

Over the past several years, significant progress has been made in evaluating the efficacy of psychotropic medications used in the treatment of PTSD. A number of placebo-controlled trials of medication for the treatment of PTSD have been conducted, which has resulted in an increase in the number of agents that can be prescribed with some confidence. In addition, open label studies and case reports continue to suggest other promising medications that likely will be tested in future controlled trials.

Another challenge in the future will be to determine whether psychotropic medications might enhance the efficacy of evidence-based psychotherapies for PTSD. While these psychotherapies are relatively brief and appear to effectively cure PTSD in many individuals, many individuals remain symptomatic after treatment. In addition, otherwise well-controlled trials of these therapies have not controlled for medication use. Thus, we cannot be sure whether medication use might have enhanced or hindered the effects of these psychological treatments in some individuals. Comparisons between the psychological and medication treatments are also difficult because active

psychological treatments are generally compared to no treatment, while active medications are compared to nonactive placebo medications that typically lead to some improvement in PTSD symptoms themselves. This could contribute to the greater apparent efficacy of psychotherapies compared to medications.

Antidepressants Used in the Treatment of PTSD

Selective serotonin reuptake inhibitors (SSRIs) Selective serotonin reuptake inhibitors (SSRIs) interfere with the reuptake of serotonin into neurons from which serotonin is released. In addition, SSRIs appear to increase brain levels of neuroactive steroids that reduce anxiety, arousal, and pain. A number of preliminary open label studies, as well as placebo-controlled double-blind studies, have shown that SSRIs such as fluoxetine, sertraline, paroxetine, and citalopram are helpful in treating core symptoms of PTSD. For example, studies of sertraline show approximately 30% reductions in PTSD symptoms. There is some evidence that the efficacy of these agents is greater either in women or in victims of civilian trauma compared to male victims of combat trauma.

Tricyclic antidepressants Tricyclic antidepressants increase brain levels of neurotransmitters such as norepinephrine and serotonin by interfering with their reuptake into neurons after their release. Tricyclic antidepressants may be helpful in some patients with PTSD in the treatment of depression, as well as in the treatment of re-experiencing and hyperarousal symptoms. However, these agents are generally less effective than either monoamine oxidase inhibitors (MAOIs) or SSRIs in the treatment of core symptoms of PTSD. The anticholinergic side effects of tricyclics appear to be less well tolerated in patients with PTSD compared to other patient groups.

Monoamine oxidase (MAO) inhibitors MAO inhibitors are medications that inhibit enzymes that break down monoamine neurotransmitters such as dopamine, serotonin, and norepinephrine. The levels of these neurotransmitters in the brain and peripheral nervous system therefore increase. MAOIs have been shown in double-blind, placebo-controlled studies to be helpful in treating re-experiencing symptoms in PTSD. The use of MAO inhibitors is contraindicated in patients with comorbid substance use because of potential life-threatening interactions with illicit drugs and alcohol. Patients on MAOIs also must adhere to a special diet devoid of foods and beverages with tyramine (an amino acid that interacts with neurotransmitters increased by MAOIs) in order to avoid potentially dangerous side effects. Many

patients are not willing or reliably able to restrict their diet in this manner.

Sleep Medications

A number of medications can be useful in promoting sleep in PTSD. These include the antidepressants trazodone, mirtazapine, and amitriptyline, atypical neuroleptics (see next section), antiadrenergic agents (see later), and drugs that target the γ -aminobutyric acid type A (GABA_A) receptor such as the benzodiazepines. Problems with tolerance frequently complicate use of the latter, however.

Atypical Neuroleptics Used in the Treatment of PTSD

Neuroleptics act by blocking the effects of neurotransmitters such as dopamine, serotonin, and norepinephrine at their receptors. Traditional neuroleptics primarily block dopamine type 2 (D₂) receptors while newer atypical neuroleptics primarily block serotonin type 2 receptors (5-HT₂) and sometimes noradrenergic α 1 or α 2 receptors. Before PTSD was formally recognized as a distinct psychiatric disorder, veterans displaying symptoms of hypervigilance, paranoia, agitation, dissociation, trauma-related auditory hallucinations, and behavioral dyscontrol were sometimes treated with traditional neuroleptics. Neuroleptic use in PTSD was thereafter discouraged due to their poor efficacy, intolerable short-term side effects, and potential for inducing long-term movement disorders. More recently, the newer atypical neuroleptics have been found to be both tolerable and efficacious over the short term in treating severe combat-related PTSD, particularly impulsive aggression, irritability, and sleep disturbance. The long-term effectiveness, tolerability, and long-term potential for side effects associated with these agents have not yet been studied, however.

Other Medications of Potential Use in the Treatment of PTSD

A variety of other medications also may be useful in treating PTSD. However, double blind, placebo-controlled studies of the efficacy of these agents either alone or in combination with other medications have not yet been completed.

Antiadrenergic agents Antiadrenergic medications such as propranolol (which blocks the effects of epinephrine at β -receptors) or clonidine (which inhibits the release of norepinephrine) have been reported to effectively treat hyperarousal and re-experiencing symptoms in PTSD. Large controlled trials of propranolol administered in the immediate aftermath of trauma for the prevention of PTSD are currently

under way. Prazosin, a noradrenergic α 1 receptor antagonist, has shown some promise in reducing nightmares in PTSD.

Anticonvulsants Preliminary studies suggest that anticonvulsants such as carbamazepine or valproic acid have variable effects on hyperarousal, re-experiencing, and emotional numbing in PTSD. Benzodiazepines (tranquilizers) may be used for the nonspecific symptoms of irritability, anxiety, and insomnia, though tolerance and dependence are often a problem. The use of benzodiazepines in patients with past alcohol or drug abuse problems may be unwise since it may serve to trigger relapse; if prescribed, careful monitoring is necessary. A recent open label trial of topiramate, an anticonvulsant that antagonizes certain excitatory glutamate receptors while enhancing the effects of GABA at a novel subtype of the GABA_A receptor, suggests that it may be beneficial and well tolerated in PTSD. Controlled trials of this agent will need to be conducted to confirm its efficacy.

Pharmacological agents under development As our understanding of the underlying neurobiology of PTSD increases, the potential for the development of pharmacological agents that counteract deleterious biological changes associated with PTSD increases. For example, studies have demonstrated an increase in the central nervous system level of the peptide (protein) neurotransmitter called corticotropin-releasing hormone (CRH) in chronically stressed animals and in combat veterans with PTSD. CRH has been shown to confer an increase in stress sensitivity and to increase the expression of defensive behaviors in many animal models. Thus, drugs that interfere with the effects of CRH at its receptors (CRH antagonists) are under development for the possible treatment of PTSD.

Similarly, recent research suggests that blood levels of a substance called neuropeptide Y (NPY) may be decreased in combat veterans with PTSD. Centrally, NPY has been found to counteract the anxiogenic effects of CRH and to be generally anxiolytic. In addition, NPY acts to inhibit the release of norepinephrine in response to stress; therefore, a decrease in blood NPY levels may contribute to the hyperactivity of the peripheral sympathetic nervous system and the related fight-or-flight behaviors seen in PTSD. Consistent with a role for NPY in modulating hyperactive stress responses, low plasma NPY levels have been found in combat veterans with PTSD, while higher plasma NPY levels are associated with better performance and decreased dissociation symptoms in military personnel undergoing intense, stressful mock interrogation trials during training. Drugs that target

the NPY system are therefore under development and are being considered for the treatment of PTSD.

Synthetic neuroactive steroids that facilitate action of the inhibitory neurotransmitter GABA at GABA_A receptors are also in development. These steroids have been shown to exert potent anxiolytic, anesthetic, and sedative actions. Recent data suggest that cerebrospinal fluid levels of such neuroactive steroids are low in women with PTSD. Finally, medications that target excitatory, glutamatergic neurotransmitter system receptors such as the N-methyl-D-aspartate (NMDA) receptor are being considered for treatment of PTSD. D-cycloserine, for instance, has been shown to enhance the rate of recovery from specific phobias and thus may facilitate extinction of conditioned fear in patients with PTSD.

Summary

Substantial progress has been made in evaluating the efficacy of a variety of psychological and medication treatments for PTSD. Given the demonstrated efficacy of combinations of psychotherapeutic interventions, it is even beginning to appear that chronic PTSD need not be considered chronic. However, there is further work to be done. Many patients with PTSD remain relatively treatment resistant. Biological as well as psychological characteristics of these trauma victims may be important determinants of treatment resistance. Future research needs to better define such factors so that current treatment techniques can be appropriately modified and new treatment approaches developed. Combining pharmacological treatments targeting specific underlying neurobiological abnormalities with psychotherapeutic approaches is likely to be one such new approach. In addition, research aimed at understanding the pathogenesis of PTSD must be continued so that better methods of PTSD prevention and intervention can be developed.

Glossary

<i>Corticotropin releasing hormone (CRH)</i>	The key hormone of the stress system secreted by the hypothalamus; it stimulates corticotropin production and secretion by the pituitary, which, in turn stimulates cortisol production by the adrenal cortex. During pregnancy, CRH is also produced by the placenta.
<i>Early-life programming</i>	Structural and functional changes in prenatal development caused by early-life environmental factors influence; these persist in the later life or the entire life span of the offspring.
<i>Glucocorticoids</i>	Hormones produced and secreted by the adrenal glands in a baseline circadian fashion and in response to stress; the main endogenous glucocorticoid in humans is cortisol.
<i>Hypothalamic-pituitary-adrenal (HPA) axis</i>	The brain-controlled activation pathway for the secretion of corticosteroid hormones during stress through a hormonal cascade.
<i>Stress</i>	A state caused by the real or perceived challenge to homeostasis, accompanied by various hormonal responses.
<i>Stress system</i>	A complex system of brain circuits and peripheral effectors that are activated during stress. Its main components are the CRH and locus ceruleus–norepinephrine (LC–NE) arousal and autonomic systems and their peripheral effectors, the

pituitary-adrenal axis and the limbs of the autonomic nervous system.

Preeclampsia/eclampsia

Pregnancy associated with disturbances in maternal placental circulation, arterial hypertension, and activation of the acute-phase reaction and blood hypercoagulability. It is a potentially lethal state, frequently associated with spontaneous premature labor and delivery; artificial induction of delivery may be necessary for its control.

Stress, the Stress System and the Hypothalamic-Pituitary-Adrenal Axis in the Nonpregnant State

Living organisms maintain a complex dynamic equilibrium (homeostasis) that is constantly challenged by intrinsic and extrinsic adverse forces or stressors. In humans, the stress response (adaptive responses of the organism to various stressors) results in the activation of a complex repertoire of behavioral and physiological responses. The main components of the stress system are the corticotropin releasing hormone (CRH) and locus ceruleus–norepinephrine (LC–NE) autonomic systems and their peripheral effectors, the pituitary-adrenal axis and the limbs of the autonomic system ([Figure 1](#)).

During stress, the hypothalamic-pituitary-adrenal (HPA) axis is activated in response to a variety of stressors, and CRH appears to mediate the metabolic, circulatory, and behavioral changes that are necessary for an effective response. CRH, produced and secreted by the hypothalamus, stimulates adrenocorticotrophic hormone (ACTH) production and secretion by the pituitary. In turn, ACTH stimulates the production and secretion of cortisol by the adrenal cortex. The regulation of these hormones is achieved by complex negative feedback mechanisms.

CRH plays an important role in inhibiting gonadotropin-releasing hormone (GnRH) secretion during stress, and via somatostatin it also inhibits growth hormone (GH), thyrotropin-releasing hormone (TRH), and thyrotropin (TSH) secretion, thus suppressing

reproductive, growth, and thyroid functions. Interestingly, these three functions depend on positive catecholaminergic input. On the other hand, the end hormones of the HPA axis, the corticosteroids, play multiple adaptive roles (Table 1). They simultaneously inhibit the CRH, LC–NE and β -endorphin systems

and stimulate the mesocorticolimbic dopaminergic system and the CRH-peptidergic central nucleus of the amygdala. In addition, they directly inhibit pituitary gonadotropin, GH, and TSH secretion. They also have direct and insulin-mediated effects on adipose tissue, ultimately promoting visceral adiposity, insulin

resistance, dyslipidemia, and hypertension (metabolic syndrome X) and direct effects on the bone, causing low-turnover osteoporosis. Central CRH via glucocorticoids and catecholamines inhibits the inflammatory reaction, whereas CRH directly secreted by peripheral nerves stimulates local inflammation.

The stress response is meant to be acute or at least of a limited duration. The time-limited nature of this process renders its accompanying antianabolic, catabolic, and immunosuppressive effects temporally beneficial and of no adverse consequences. The chronic, excessive, or deficient activation of the stress system, on the other hand, may lead to abnormal reactivity of the HPA axis, mostly in the form of increased or decreased cortisol secretion. In both cases, pathological adaptation may have detrimental effects on the organism.

The Maternal Hypothalamic-Pituitary-Adrenal Axis during Pregnancy

Pregnancy is a period of hypercortisolism. From weeks 8–10 of gestation on, CRH is also produced by the placenta and secreted primarily into the maternal and also into the fetal circulation. Placental CRH (pCRH) has the same biological activity as hypothalamic CRH (Table 2). pCRH has been postulated to stimulate maternal pituitary ACTH release and cortisol secretion, thereby contributing to pregnancy-associated hypercortisolemia. Paradoxically, cortisol stimulates the synthesis and release of pCRH in a positive feedback regulation fashion. pCRH secretion is also stimulated by inflammatory cytokines, mechanical stretch, and anoxic conditions and therefore by inflammatory and noninflammatory stress, including the stress of preeclampsia or eclampsia. The alterations mentioned result in a shift from normal negative feedback regulation of the maternal HPA axis to a feed-forward mechanism of peripherally produced pCRH, which stimulates adrenal cortisol secretion (Figure 2).

Generally, under normal conditions, circulation pCRH is inactivated to a large extent by a CRH

binding protein (CRH-BP). During the second half of pregnancy, plasma CRH levels increase exponentially, whereas the CRH-BP concentration starts decreasing at about weeks 33–34 of gestation. The outcome is even higher levels of bioactive CRH, which reaches a peak during labor and delivery and then rapidly decreases postpartum. The increase in CRH levels in the mother's plasma toward the end of pregnancy is normal. HPA axis hormones (CRH; ACTH; corticosteroids; and dehydroepiandrosterone sulfate, DHEAS) are involved in the timing of the onset of the birth process in humans. pCRH causes vasodilation of the fetoplacental circulation by activating nitric oxide synthase and participates in labor by stimulating the secretion of prostaglandin E2a and prostaglandin E2 by the fetal membranes and by promoting the constriction of myometrial cells. At the end of normal pregnancy, the simultaneous stimulation of organ maturation and initiation of parturition constitute a positive effect of a feed-forward mechanism. However, the premature activation of this system may result in preterm labor and delivery. This is supported by evidence of an earlier association between prematurely raised blood pCRH (and decreased CRH-BP) levels in pregnant women who had a preterm delivery. Both preeclampsia and eclampsia are characterized by prematurely elevated levels of pCRH and spontaneously premature labor and delivery.

At the end of parturition, the placental source of CRH is lost; thus, the hypercortisolism of pregnancy is followed by a transient suppression of hypothalamic CRH secretion in the postpartum period. The readjustment of the HPA axis and the postpartum recovery of hypothalamic CRH activity remains poorly characterized and varies among women. The hypothalamic-pituitary-ovarian axis is suppressed

(1998), Interactions between the hypothalamic-pituitary-adrenal axis and the female reproductive system: clinical implications, *Annals of Internal Medicine* **129**, 229–240.

postpartum and does not recover for approximately 4–6 weeks. Both hypothalamic CRH hyposecretion and abrupt estrogen withdrawal may explain the postpartum blues or depression and autoimmune phenomena frequently seen during this period (Figure 3). Estrogen administration has been shown to ameliorate postpartum depression, probably by returning to normal the secretion of the suppressed CRH neuron.

During pregnancy, ACTH and cortisol continue to be secreted in a pulsatile and circadian fashion, whereas the secretion of pCRH is pulsatile but not circadian. The lack of circadian correlation between CRH and ACTH/cortisol is not surprising because the major part of CRH comes from the placenta, is bound to CRH-BP, and has limited action on the maternal corticotrophs. Moreover, another secretagogue, possibly arginine vasopressin (AVP), released at the median eminence from terminals of the parvocellular neurons, may be important in regulating pulsatile and circadian ACTH secretion during this period.

The Hypothalamic-Pituitary-Adrenal Axis of the Fetus

Fetal cortisol is important for the maturation of virtually all fetal organ systems. The importance of the increase in fetal cortisol secretion for the maturation

of the fetal lung and other systems is well established. The fetal HPA axis is regulated through negative feedback starting early in gestation. In a later stage of pregnancy, pCRH enters the fetal circulation via the umbilical vein. Maternal HPA axis hormones also stimulate the placenta to produce CRH. pCRH stimulates the fetal HPA axis to produce and secrete ACTH, cortisol, and androgens (DHEAS, which at the placenta is converted to estriol). Subsequently, fetal cortisol enters the placental circulation via the umbilical vessels and further stimulates the production of pCRH. This way, the fetal HPA axis is also regulated by a feed-forward mechanism at the end of pregnancy. This results in a large increase in cortisol through which maturation of the fetal organs is enhanced.

Maternal-Placental-Fetal Stress Physiology

It is most likely that maternal stress influences the fetus through (stress) hormones. The following three mechanisms have been proposed, which may operate simultaneously and may amplify one another's effects.

1. Reduced uteroplacental blood flow. Corticosteroids and catecholamines exert strong effects on peripheral blood vessels, and the placenta is replete

with receptors for these hormones. The activation of the sympathetic nervous system by stress may lead to reduced blood flow to the uterus and fetus, and it may contribute to fetal growth restriction.

2. Transplacental transport of maternal stress hormones. The human fetus is relatively protected against direct exposure to high cortisol concentrations. In the placenta, 50–90% of maternal cortisol is converted to the biologically inactive cortisone by the enzyme 11 β -hydroxysteroid dehydrogenase (11 β -HSD2). This enzyme protects the fetus for most of the pregnancy. However, under specific conditions (e.g., if the maternal cortisol concentration is very high, if the activity of 11 β -HSD2 is reduced or impaired due to interindividual differences, or when the placenta is immature in early pregnancy or poorly functioning), maternal cortisol is not completely inactivated in the placenta and the fetus is directly exposed to its detrimental actions. Interestingly, in normal pregnancy, a few days before normal labor the 11 β -HSD2 spontaneously decreases to further prepare the fetus for the extra-uterine life.

3. Secretion of CRH to the fetus. A diminished supply of nutrients and oxygen (hypoxemia) for any reason, including infection, inflammation, preeclampsia, eclampsia, starvation, or placental insufficiency, may cause a stress response in the fetus. This involves increased secretion of pCRH that, in turn, contributes to the feed-forward mechanisms at either side of the placenta and accelerates labor and delivery.

Effects of Prenatal and Perinatal Stress

The stress-induced activation of the HPA axis during pregnancy can be expected to have serious negative implications for the mother (pregnancy complications, preterm delivery, problems in lactation, and increased vulnerability to mood disorders and autoimmune phenomena postpartum), the fetus's development (intrauterine growth retardation, immaturity, neurological damage, etc.), and subsequent sequelae in the adult life of the newborn infant.

Maternal Stress: Pregnancy Complications and Preterm Delivery

Recent well-controlled human studies indicated that pregnant women with high stress and anxiety levels are at increased risk for spontaneous abortion, preeclampsia, and preterm labor. The HPA axis hormones (CRH, ACTH, corticosteroids, and DHEAS) are involved in the timing of the onset of birth in humans (rapid increase in free pCRH during the last 2–4 weeks of pregnancy). pCRH initiates, through an increase in DHEAS (the precursor of estrogens), a

cascade of events that may lead to increased uterine activity and eventually labor and delivery. The fetal DHEAS reaches the placenta, where it is converted to estrone (E_1) and estradiol (E_2) and, after 16-hydroxylation in the fetus's liver, also to estriol (E_3). The increase in E_2 and E_3 contributes to the onset of term and preterm delivery (through the stimulation of oxytocin, oxytocin receptor, gap junction, and prostaglandin synthesis).

Maternal stress and fetal stress or hypoxia increase maternal and/or fetal plasma cortisol levels and, because of its positive stimulatory effect, the latter causes an increase in pCRH. Maternal and fetal stresses are also associated with an increase in NE, angiotensin II, and AVP, all compounds that stimulate CRH release in the hypothalamus as well as in the placenta. Fetal distress and preterm delivery may also be driven by amniochorionic and maternal systemic inflammation. Infections and high levels of interleukins may also stimulate CRH secretion and the stress system. Women with preterm delivery, especially those with infections, show an increase in cytokines such as interleukin (IL-)1, tumor necrosis factor (TNF-) α , and IL-6, which is also secreted by the placenta in response to IL-1 and TNF- α . The activation of the cytokine network may lead to increased placental apoptosis and preterm delivery.

Under abnormal circumstances (preeclampsia, eclampsia, threatened preterm delivery, or maternal stress), all these alterations may be initiated prematurely. In mothers who deliver preterm, the hormone increases might be noticeable even in the second trimester, indicating that the trajectory toward preterm delivery may start early in pregnancy and may be recognizable, potentially leading to the development of preventive interventions. This issue is still in need of further investigation. Potent CRH antagonists might be used as labor retardants.

Maternal Stress and Lactation

Lactating women interact more positively with their babies, and nursing mothers (vs. bottle-feeding mothers) are more likely to describe positive mood states and less anxiety. Successful lactation involves the oxytocin-mediated milk ejection reflex and neuroendocrine adaptations of the HPA and gonadal axes. A recent study conducted in breast-feeding women reported decreased plasma ACTH, cortisol, AVP, epinephrine, and glucose responses to treadmill stress tests, suggesting that, under normal conditions, during lactation there is a selective inhibition of the hypothalamic stress response (stress hyporesponsive period). Central actions of oxytocin have been implicated as a cause of the downregulation of HPA

axis reactivity. On the other hand, it has long been known that stress and hormonal products of the HPA axis can influence the release and actions of oxytocin. Milk ejection is inhibited by stressful experiences, suggesting that oxytocin secretion in women could also be inhibited by stress.

Maternal Stress and Increased Vulnerability to Mood Disorders and Autoimmune Phenomena Postpartum

Epidemiological studies indicate that childbearing represents a period of vulnerability to depressive symptomatology in women. Postnatal depression is a significant and serious illness with a reported incidence of approximately 14%, and a further 30% of women experience an adjustment disorder and anxiety following childbirth. The impact of postpartum depression and psychosis on family life is pervasive, and its capacity for causing long-term harm in children is disturbing. The *Diagnostic and Statistical Manual of Mental Disorders* (4th edn.; DSM IV) indicates that postpartum disorders are distinguished not by their phenomena but by their timing. Any major depressive, manic, or mixed episode; bipolar I disorder or bipolar II disorder; or brief psychotic disorder should get a postpartum specifier if it occurs within the postpartum period.

The abrupt CRH withdrawal once the placenta is delivered and its impact on the mother's HPA axis equilibrium may be a major contributing factor to the development of postpartum blues or depression. It is possible that the development of postpartum blues or depression is related to the prolonged or exaggerated suppression of hypothalamic CRH during the postpartum period because the occurrence of postpartum depression has been found to be related to fluctuations in the levels of glucocorticoids. The resetting of the HPA axis and postpartum recovery of the CRH activity remains poorly characterized and varies among women. Moreover, stress affects glucocorticoid levels and can influence estradiol levels in nonpregnant and pregnant females. The sudden withdrawal of estradiol following parturition is also considered an important pathophysiological mechanism of postpartum disorders. In support of this hypothesis, estrogen is an effective treatment for postnatal depression. The newborns of mothers with prepartum and postpartum depressive symptoms have elevated cortisol and norepinephrine levels and lower dopamine levels.

The transient suppression of hypothalamic CRH secretion in the postpartum period might also explain the increased vulnerability to autoimmune phenomena at this period. A defective HPA axis might lead

to relative resistance to infections and neoplastic disease and increased susceptibility to autoimmune and inflammatory disease, such as Hashimoto's thyroiditis, rheumatoid arthritis, and multiple sclerosis.

Prenatal Stress and Its Effects on Fetal Development

Fetal cortisol levels are increased in human fetuses showing intrauterine growth retardation or in pregnancies complicated by preeclampsia, implicating endogenous cortisol in retarded fetal growth. Chronic maternal stress is associated with reduced fetal heart rate variability, which is an indicator of fetal maturation. Most studies assessing the impact of both acute and chronic stress in the fetus have measured changes in heart rate and fetal movements. Experimental studies have demonstrated a relation between specific episodes of maternal psychological stress and exacerbation of fetal asphyxia *in utero*. Experiencing stress during pregnancy leads to the birth of babies with low birth weight, congenital malformations, or growth retardation (reduced head circumference, in particular).

Stress also increases the risk of the infant's developing diseases in subsequent periods of life. Antenatal glucocorticoid administration has been linked with higher blood pressure in adolescence and subtle effects on neurological function, including reduced visual closure and visual memory. Multiple doses of antenatal glucocorticoids given to women at risk of preterm delivery were associated with reduced head circumference and an increased risk of externalizing behavior problems, distractibility and inattention in the offspring.

The Long-Term Programming Hypothesis

The importance of a good quality of psychoaffective communication between mother and child during pregnancy has been shown to be decisive for fetal growth, the perinatal period, and further development of the child. Early-life environmental factors influence prenatal development and may cause structural and functional changes, which persist for the life span. This organizational phenomenon is termed early-life programming or fetal programming of adult disease. This hypothesis proposes that a stimulus or insult acting during critical periods of growth and development may permanently alter tissue structure and function. Genes and environment are no longer considered to exert separate influences. Development is viewed not as a gradual elaboration of an architectural plan preconfigured in the genes but, rather, as a dynamic interdependency of genes and

environment, characterized by a continuous process of interactions in a space- and time-dependent manner. Evidence from both human and animal studies suggests that manipulating the environmental experience of the fetus can induce many diseases of adult life. Programming agents seem to include nutrients, growth factors, cytokines, and hormones, all of which can be altered by stress.

Numerous studies, initially in the United Kingdom and then worldwide, revealed an association between lower birth weight and the subsequent development of the common cardiovascular and metabolic disorders of adult life, notably hypertension, insulin resistance, type 2 diabetes, hyperlipidemia, and atherosclerotic cardiovascular diseases. Thus, early-life events altering birth weight are important predictors of adult morbidity. In addition, postnatal catch-up growth also appears to be predictive of the risk of adult cardiovascular disease, suggesting that it is the restriction of intrauterine growth (caused by overexposure to glucocorticoids) that is pathophysiologically important.

The human HPA axis also appears to be programmed by the early-life environment. Higher plasma and urinary glucocorticoid levels are found in children and adults who were of low birth weight. Two major environmental hypotheses have been proposed to explain the mechanism by which low birth weight is associated with adult disease: fetal nutrition and overexposure of the fetus to glucocorticoids. There is no doubt that in developing countries maternal diet can affect birth weight and may be extremely important in mediating intergenerational effects on birth weight and adult size. Glucocorticoid administration during pregnancy is well documented to both reduce offspring birth weight and alter the maturation of organs (hence, their use to accelerate fetal lung maturation in premature labor). Moreover, antenatal exposure to endogenous or exogenous glucocorticoids produces permanent hypertension, hyperglycemia, hyperinsulinemia, altered behavior, and neuroendocrine responses throughout the life span (in animal experiments).

Fetal undernutrition and fetal glucocorticoid overexposure may be linked by a common mechanism. Processes underlying fetal programming include the determination of the set point of the HPA axis and of tissue glucocorticoid receptor (GR) expression. The molecular mechanisms may reflect permanent changes in the expression of specific transcription factors, key among which is the GR itself. The differential programming of the GR in different tissues reflects effects on one or more of the multiple tissue-specific alternate first exons/promoters of the GR gene. The

proposed mechanisms by which overexposure to glucocorticoids prenatally lead to cardiovascular and metabolic disorders of adult life are as follows:

- **Hypertension and cardiovascular disease:** Prenatal glucocorticoid exposure leads to irreversible reductions in nephron number, fetal and adult vascular responses to vasoconstrictors, enhancing endothelin-induced vasoconstriction and attenuating endothelium-dependent vasorelaxation, indicating microvascular dysfunction. Renin–angiotensin system receptor density and tissue synthesis are also affected. Prenatal glucocorticoid exposure also alters the development of cardiac noradrenergic and sympathetic processes.
- **Liver and pancreas:** Prenatal overexposure to exogenous or endogenous glucocorticoids programs permanent hyperglycemia – particularly hyperinsulinemia – in the adult offspring, effects that are confined to the last third of gestation. Glucocorticoids regulate the expression of critical hepatic metabolic enzymes, notably phosphoenolpyruvate carboxykinase (PEPCK), which catalyses a rate-limiting step in gluconeogenesis. Prenatal undernutrition impairs pancreatic β -cell development, reducing β -cell mass and causing glucose intolerance. Fetal pancreatic insulin content correlates inversely with fetal corticosterone levels.
- **Adipose tissue:** Antenatal corticosteroid exposure seems to program fat metabolism, causing a marked increase in GR expression selectively in visceral adipose tissue, which contributes to both adipose and hepatic insulin resistance. Leptin concentrations in human fetal cord blood correlate directly with body weight and adiposity at birth.

Altered Regulation of Hypothalamic-Pituitary-Adrenal Axis after Prenatal Stress and Its Influence on the Fetal Central Nervous System

There is abundant evidence of an overactive and dysregulated HPA axis in the offspring of prenatally stressed animals. Prenatally stressed animals have higher basal blood glucocorticoid levels, and when exposed to a stressful stimulus, their hormonal response is more rapid, stronger, and more prolonged, indicating that the normal negative feedback mechanism of the HPA axis is heavily impaired. In addition, alterations have been found in almost all known regulatory and neurotransmitter systems in the brain, including the opioid, cholinergic, serotonergic, dopaminergic, GABA-ergic, and noradrenergic systems. These alternations could underlie some of the behavioral and physiological effects observed after prenatal stress and may further affect later stress responses.

Three mechanisms can explain the overactivity and altered feedback regulation of the HPA axis (increased levels of HPA axis hormones affect fetal central nervous system development and, especially, brain GR development): (1) the downregulation of receptors in the hippocampus, hypothalamus, pituitary, or adrenal glands; (2) the decreased sensitivity of the receptors at any of these levels; and (3) the alteration in CRH levels or the altered levels or affinity of plasma-binding proteins. The maternal HPA axis is involved in early neuroendocrine programming of the offspring.

The hippocampus appears to be particularly vulnerable to insult during early development because its pyramidal neurons contain a high concentration of GRs that are highly sensitive to either hypercortisolemia caused by severe stress or to exposure to exogenous glucocorticoids. Another neural structure that may contribute to increased responsiveness of the HPA axis following prenatal stress is the amygdala, a key locus for its effects on fear and anxiety. The content of CRH appeared to be substantially increased in the amygdala of prenatally stressed rats compared to levels in control animals. These increased levels of CRH are associated with increased emotionality, fear, and anxiety-like behaviors and facilitate stress-induced behavior and autonomic activation.

Moreover, prenatal glucocorticoid exposure contributes to schizoaffective, attention deficit hyperactivity, and extrapyramidal disorders. Stressful events in the second trimester of human pregnancy have been associated with increased incidence of offspring schizophrenia.

Diagnostic Issues

Etiology

Glossary

<i>Circadian oscillator</i>	A pacemaker located in the superchiasmatic nucleus of the hypothalamus with an output that repeats about once per day.
<i>Dysphoric mood</i>	A symptom of depression; feeling sad, despondent, discouraged, unhappy, anxious, or irritable.
<i>Entrainment</i>	The process by which the circadian oscillator becomes synchronized with the external environment.
<i>Follicular phase</i>	Also called the proliferative phase or estrogenic phase, the follicular phase of the menstrual cycle lasts from the first day of menstruation until ovulation. As assessed by the secretion of luteinizing hormone (LH), gonadotropin-releasing hormone (GnRH) is secreted from the hypothalamus in a pulsatile manner at a frequency of once per 90 min during the early follicular phase and increasing to once per 60–70 min. Follicle-stimulating hormone (FSH) is secreted by the anterior pituitary, and its concentrations in plasma increase from the first day of the cycle.

Luteal phase

The rise in FSH levels can be attributed to a decrease in progesterone and estrogen levels at the end of the previous cycle and the subsequent removal of inhibition of FSH by these ovarian hormones. FSH stimulates the development of 15–20 follicles each month and stimulates ovarian follicular secretion of estradiol. Estrogen levels peak toward the end of the follicular phase of the menstrual cycle, at which point estrogen exerts positive feedback on the hypothalamic-pituitary-gonadotrope system, thereby triggering the preovulatory LH surge.

Approximately the second half of the menstrual cycle occurring after ovulation during which there is a decrease in frequency and increase in amplitude of time, ovarian steroid, and pulsatile release LH (and presumably GnRH) secretion. The luteal cells of the corpus luteum produce progesterone, the plasma levels of which peak by the middle of the luteal phase (days 20–22). By day 28, the corpus luteum has regressed with a consequent decrease in the output of estrogen and progesterone. The latter causes local ischemia and subsequent necrosis of the endometrium (i.e., menstrual flow).

Zeitgeber

German for time giver; a regular, external cue that synchronizes the internal clock to environmental cues; light is the most powerful zeitgebers in humans.

Premenstrual dysphoric disorder (PMDD) is a clearly defined syndrome that is often referred to as premenstrual syndrome (PMS) among the nonmedical population. As delineated in the *Diagnostic and Statistical Manual*, 4th edition (DSM-IV-TR), five symptoms are required to make the diagnosis of

Table 1 Diagnostic criteria for premenstrual dysphoric disorder

A. In most menstrual cycles during the past year, at least five of the following symptoms must have been present most of the time during the last week of the luteal phase and disappear within a week after the onset of menstruation. At least one of the symptoms must be one of the first four.

1. Feeling sad, hopeless, or self-deprecating
2. Feeling tense, anxious or on edge
3. Marked lability of mood interspersed with frequent tearfulness or increased sensitivity to rejection
4. Persistent irritability, anger, and increased interpersonal conflicts
5. Decreased interest in usual activities
6. Difficulty concentrating
7. Feeling fatigued, lethargic, or lacking in energy
8. Marked changes in appetite, which may be associated with binge eating or craving certain foods
9. Hypersomnia or insomnia
10. A subjective feeling of being overwhelmed or out of control

B. The symptoms must cause an obvious and marked impairment in the ability to function socially or occupationally.

C. The symptoms may be superimposed on another disorder but are not merely an exacerbation of the symptoms of another disorder, such as major depression, panic disorder, dysthymia, or a personality disorder.

D. Criteria A, B, C, and D must be confirmed by prospective daily self-ratings during at least two consecutive symptomatic cycles. (The diagnosis may be made provisionally prior to this confirmation.)

From the American Psychiatric Association (2000). *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, text revision. Washington, D.C.: American Psychiatric Association, with permission.

PMDD, and at least one symptom must be a moderate to severe mood symptom (see [Table 1](#)). The criteria for PMDD are more stringent and delineate increased specificity and severity of premenstrual symptoms with an emphasis on affective symptoms (see [Table 1](#)). The criteria for PMDD are stringent and delineate increased specificity and severity of premenstrual symptoms with an emphasis on affective symptoms (see [Table 1](#)). Symptoms typically begin in the late luteal (premenstrual) phase of the menstrual cycle, which is associated with declining estrogen and progesterone levels from the degenerating corpus luteum. Premenstrual symptoms typically remit within the first few days of the follicular phase, when estrogen levels increase as a result of follicular growth. The diagnosis of PMDD requires documentation of luteal phase timing of symptoms and a symptom-free interval from approximately day 4 of menses to the onset of ovulation. The National Institute of Mental Health Premenstrual Syndrome Workshop (1983) specified that a 30% change in symptom severity during the luteal phase is required for a PMDD diagnosis. In addition, a diagnostic requirement is that symptoms must cause functional impairment.

Diagnostic Issues

R. T. Frank first identified physical, psychological, and behavioral changes corresponding to monthly changes in reproductive hormones in 1931. However, public awareness of the concurrent change in mood with phases of the menstrual cycle has increased

dramatically over the past two decades. The media has disseminated a wide body of information shaping a societal notion of what is popularly termed premenstrual syndrome (PMS). Definitions for PMS have varied widely. Typically, PMS refers to a large number of symptoms, including irritability, tension, fatigue, dysphoria, distractibility, impaired motor coordination, changes in eating and sleeping, and libido changes, which occur in the late luteal phase and remit after the beginning of menstruation. Up to 90% of women experience some premenstrual symptoms, and 50% of women may experience many symptoms together, thus comprising a syndrome.

Many women experience mood disruptions or physical complaints during the late luteal phase. For this reason, the PMDD diagnosis has been controversial among psychiatrists, psychologists, gynecologists, and sociologists. One reason for the ambiguity may be the failure to distinguish normal from pathological premenstrual mood disturbance. Unlike other psychiatric syndromes, the remission and relapse of premenstrual symptoms is connected to a physiological process, the menstrual cycle. Every woman does not experience a pathological premenstrual mood disorder, however. Furthermore, there are discrepant views in defining depression as a categorical versus spectrum illness. Depression can be defined as a discrete, all-or-none variable or on a continuum of symptom severity. Thus, the differentiation between the normal and pathological is important in terms of investigative research, interdisciplinary discourse, as well as treatment.

Premenstrual criteria were included in the appendix of DSM-III-R as late luteal phase dysphoric disorder (LLPDD), and they are currently included as PMDD in the appendix of the DSM-IV-TR as a depressive disorder, not otherwise specified. Some researchers have postulated that moving PMDD into the depressive disorders not otherwise specified section of the DSM-IV has reinforced the view that PMDD is depression, rather than a unique disorder. Moreover, the treatment of PMDD with selective serotonin reuptake inhibitors (SSRIs) may be treating symptoms of depression rather than the etiological disturbance; thus, treatment may provide little information on the nature of the disorder and raises the problem of comorbidity with other mood disturbances (e.g., major depressive disorder).

Besides emotional distress, the disturbance must cause impairment in occupational or social functioning. Also, the mood disturbances must begin during the late luteal phase and remit at the follicular phase; this trend of mood fluctuation must occur over at least two consecutive cycles. Because retrospective ratings may not be accurate due to an expectation bias, premenstrual trends must be documented by daily mood ratings. In the United States, approximately 3–5% of women are thought to experience symptoms that meet criteria for PMDD. Even with the DSM-IV-established criteria, debate over defining criteria of PMDD is ongoing. The requirement of absence of symptoms postmenstrually may be unreasonably conservative, and the criterion for premenstrual interference in daily activities contributes little to the diagnosis of PMDD. Poor classification proves to be particularly problematic because, over time, untreated PMDD becomes progressively more severe, and episodes of dysphoria extend in duration. For this reason, women diagnosed with PMDD are vulnerable to developing major depressive disorder at a later date.

Etiology

Various disciplines conceptualize the etiological basis of premenstrual mood disturbance. Biological theorists maintain that premenstrual symptoms originate from the biological reactivity or sensitivity to reproductive hormones. Psychological theorists suggest that premenstrual symptoms arise from the maladaptive response of the individual to the environment. Social theorists assert that the social, patriarchal environment elicits symptoms. Regardless of the etiological model, hormonal changes associated with the menstrual cycle are likely to serve as contributory factors to mood disruption.

Biomedical Model

Investigators and clinicians have recognized the spectrum of premenstrual mood: symptoms ranging from mild to severe. Those with severe symptoms have a decreased ability to function effectively and meet criteria for PMDD. Rather than psychosomatic origins, researchers have investigated physiological underpinnings to the disorder that are expressed in mood and behavior, that is, conceptualized as a somato-psychic illness.

Estrogen and progesterone Research in this area began with the hypothesis that the absolute amount of estrogen (E2) and progesterone (P4), e.g., P4 deficiency, E2 excess, were responsible for mood disturbances. Inconsistencies in research findings have called this hypothesis into question. The rate of hormonal change, however, may play an important role in the pathogenesis of the disorder. Schmidt and colleagues examined the role of E2 and P4 by testing the effects of ovarian suppression with leuprolide, an agonist analog of gonadotropin-releasing hormone, versus placebo in women with and without PMS. The authors found that leuprolide caused a significant decrease in symptom scores for women with PMS compared with placebo treatment. In a subsequent phase of the study, Schmidt and colleagues administered a conjunct hormone therapy (leuprolide plus estradiol or progesterone) to the women with PMS whose symptoms responded to ovarian suppression, which resulted in a significant recurrence of symptoms. Thus, baseline levels of gonadal steroids or changes in hormone levels triggered a change in mood in women sensitive to mood instability. This study suggests that the occurrence of PMS symptoms may represent an abnormal response to normal hormonal changes. In addition, it suggests that E2 and P4 variations likely exert their influence on mood indirectly rather than directly. The central nervous system (CNS) is thus a nontraditional target for sex steroids.

Other neuroendocrine variables Research also suggests that abnormal fluctuations in thyroid, cortisol, prolactin, mineralocorticoids, prostaglandins (PGs), and endogenous opiates correspond to mood changes during the menstrual cycle. In addition, women with PMDD have a brief, transient, heightened cortisol response to ovine (o) corticotropin-releasing hormone (CRH) stimulation, blunted cortisol responses to serotonergic agonists in the late luteal phase, and lower evening plasma cortisol levels. Alterations in phase but not amplitude measures of cortisol have been found in women with PMDD during the

menstrual cycle. These findings suggest a physiological dysfunction between the hypothalamic-pituitary-adrenocortical (HPA) and the hypothalamic-pituitary-ovarian (HPO) axis for women with PMDD. This relationship may be complex and include a variety of other systems in its interaction.

Neurotransmitters Current research suggests that neurotransmitter abnormalities in PMDD are similar to those implicated in major depressive disorder. Specifically, PMDD patients have been differentiated from normal control patients by deficiencies in the serotonergic system. Investigators have found that women with PMDD have reduced platelet uptake of serotonin 1 week before menstruation, low whole blood serotonin during the last 10 days of the menstrual cycle, and an abnormal response to tryptophan loading in the late luteal phase. SSRIs (e.g., fluoxetine, sertraline, paroxetine, fluvoxamine) have been found to be efficacious in the treatment of PMDD. The efficacy of this pharmacological class is further evidenced by the FDA approval of fluoxetine and sertraline for PMDD. Recent work has shown that fluoxetine, citalopram, clomipramine, and sertraline can be effective if administered intermittently during the luteal phase. Further work is necessary to corroborate these findings. This medication regimen may be preferable to some women who do not wish to take chronic medication for a periodic condition. Women on a luteal dosing schedule generally reach response rates of 65%, with some women experiencing no significant benefits. This response rate may be reduced by nonadherence with a luteal phase dosing regimen.

In addition to serotonin, norepinephrine has been examined as another neurotransmitter that might contribute to PMDD. However, trials comparing fluoxetine to bupropion, sertraline to desipramine, and paroxetine to maprotiline demonstrate that augmenting noradrenergic activity alone is not effective for the treatment of PMDD.

Circadian rhythms Besides antidepressant medication, sleep and light therapies also have been found to be beneficial in reducing symptoms. The efficacy of these treatments is based on a chronobiological hypothesis of depression. Chronobiological investigations indicate that people with major depressive disorder may have disruptions in the internal regulation of rapid eye movement (REM) sleep propensity, temperature, cortisol, and melatonin, which occur throughout the 24-h daily cycle. Furthermore, the oscillator regulating these circadian rhythms may be desynchronized with the sleep-wake cycle. External

cues, such as bright light, play an important role in the modulation and synchronization of these circadian rhythms. For example, exposure to 500 lux of light acutely suppresses melatonin secretion, a marker for circadian phase position. Light also shifts circadian rhythms and melatonin. Research indicates that patients with affective illness may be supersensitive to the suppressive effects of light on melatonin secretion, possibly due to inadequate exposure to daytime light; they may have altered amplitude of melatonin secretion and body temperature.

There may be differences between men and women in the regulation or expression of circadian rhythms. Compared with men, menstruating women have a shorter free-running period (i.e., length of time of a rhythm in an environment free of external cues, such as light), longer sleep duration, and lower amplitude in body temperature that varies with phases of the menstrual cycle. These findings suggest that reproductive hormones (including testosterone) affect circadian rhythm amplitude and synchronization. Indeed, comparative studies in rodents show that estrogen advances and progesterone delays circadian rhythms. Estrogen also appears to enhance synchronization between the oscillators.

Thus, fluctuations of menstrual cycle hormones may alter circadian rhythmicity. Instability of circadian rhythms resulting from changing reproductive hormonal levels may increase the risk for depression in some women. Chronobiological hypotheses contend that disrupted circadian rhythmicity is a factor contributing to depression. Women with PMDD have been reported to have decreased melatonin amplitudes, higher nocturnal body temperatures, and disturbances in the timing and amplitude of prolactin and thyroid-stimulating hormone (TSH) secretion. Also, the offset and duration of the melatonin rhythm may be disturbed and show an abnormal response to light. Light and sleep therapies may relieve PMDD symptoms by helping to realign underlying circadian clocks.

Psychological Model

In this model, women experiencing pathological premenstrual symptoms are distinguished from healthy women on the basis of the way they perceive or react to the environment. Therefore, treatment of PMDD is often directed toward physical activity, psychotherapy, relaxation training, support groups, and stress management.

One psychological model has studied PMDD from a state-dependent learning perspective, while biological markers tend to be trait dependent. Compared

with healthy subjects, women with menstrually related mood disorders report more negative life events and greater distress associated with those events only in the late luteal phase of the cycle. Thus, symptoms are conceptualized as occurring in an experiential state, such as the late luteal phase, which is characterized by affective and cognitive components. In support of the state-dependent model, women with severe premenstrual symptoms were more likely to use emotionally based coping techniques (i.e., catharsis) in the premenstrual phase than other strategies, such as cognitive reappraisal. Also during this phase, women with premenstrual dysphoria may be more likely than healthy controls to seek social support when perceiving daily stressors as uncontrollable.

Other findings fail to support the state-dependent hypothesis. Woods and colleagues suggested that a general stressful life context predicts premenstrual symptoms more than stress experienced during a particular menstrual cycle phase. A stressful milieu was a large predictor of perimenstrual symptoms and especially negative affect. Major life stressors play an important role in the development of depressive symptoms; however, the cumulative effect of daily stressors may be more influential in the generation of global premenstrual symptoms.

Type of stressor may also affect the manifestation of symptoms. For example, some research indicates that women with premenstrual dysphoria experience negative interpersonal interactions. Kuczmierczyk, Labrum, and Johnson found that women with PMDD perceive their work and especially their family lives as more stressful. Increased conflict and less self-sufficiency and assertiveness were noted in family environments of PMDD patients, which suggest that enmeshed and rigid family structures may have a role in the development of PMDD. These types of family structures have been previously implicated in other somatization processes.

In addition to disturbances in mood, women with PMDD may experience physical and cognitive changes. Cognitive deficits in major depression have been well documented and often include disturbances in attention, forgetfulness, psychomotor retardation, and proneness to confusion. In some cases, these cognitive disturbances may be secondary to mood disturbances. However, in the case of PMDD, the role reproductive hormone fluctuation may have on memory and cognitive functioning recently has been the focus of several studies. In healthy women without psychiatric illness, performance on neuropsychological tests has been found to vary with the monthly fluctuation in reproductive hormones. High levels of E2, as experienced in the late follicular phase, may

elevate performance on automatization abilities, perceptual motor speed, mental arithmetic, and verbal memory. Lower levels of E2, as experienced during the menstrual phase, may be associated with higher performance on visuospatial tasks. The majority of these effects have been subtle and were not able to be replicated; this effect may be due to difficulties in documentation and measurement of ovulation, plasma hormone levels, mood symptoms, and individual variation in cycle length. Furthermore, cyclic performance changes are minor and are unlikely to interfere with normal functioning.

Social Model

From the earliest times, various facets of women's personalities, capabilities, and moods have been attributed to menstruation. Instability, resulting from women's reproductive cycles, has been used to justify denying women equal access to education and employment. One feminist model maintains that premenstrual syndrome pathologizes a naturally occurring phenomenon. Theorists state that high prevalence rates of premenstrual symptoms support this assumption and that the distinction of a separate pathological disorder is a spurious dichotomy. Based on historical comparisons of PMS and hysteria, writers have suggested that the use of a biological explanation for this disorder may legitimize societal prejudices. Furthermore, social theorists state that the medical model may pathologize normal biological processes and oversimplify women's feelings, problems, and conflicts through the diagnosis of PMDD. In fact, medical investigations have revealed that increases in cyclicity can be viewed as adaptive because it leads to homeostasis, stabilization, and longevity in life. Thus, it is the diagnosis of PMDD that leads to the medicalization of women's experiences of the menstrual cycle and not the cycle-related changes themselves. It is suggested that PMDD is a socially constructed disorder rather than a psychiatric disorder.

Since Western society is a contributory factor in this model, research on the prevalence of PMDD in other cultures is of importance in understanding the universality of symptoms. A limited number of studies have examined symptoms of PMDD in non-Western societies. This research has been plagued by a number of important methodological concerns and questionable validity of instruments that have been translated for use in populations other than those in which they were developed. In addition, the sociopolitical position of women in other cultures and their societal beliefs and expectations about menstruation are difficult to quantify and thus have not been taken

into account. Despite these difficulties, cross-cultural studies are of interest in considering the relative importance of biological versus sociological factors in the etiology of PMDD. Investigative studies have indicated a widespread variance in the type and severity of premenstrual symptoms experienced, which supports the interpretation of normal cyclical change. Eriksen found that women in developing countries tended to report shifts in mood associated with the onset of menstruation or throughout the menstrual cycle. Several studies have found reports of higher rates of somatic than affective symptoms in populations outside the United States, suggesting that culture may influence the symptoms that women notice, as well as the symptoms they determine to be problematic during the premenstrual period. As a result of these observed cross-cultural differences, menstrual socialization has been proposed as a determinant of premenstrual complaints. These findings suggest that PMDD is a culture-bound syndrome specific to Western cultures in which most women have been socialized to have negative expectations about menstruation. More specifically, it is argued that North American culture and media perpetuate the idea that the premenstrual period will be associated with negative affect and mood instability, causing women to interpret normal physiological changes that are essentially neutral in nature to have negative connotations.

Emergence of a Biopsychosocial Model

Since the relatively recent invention of radioimmunoassays, biomedical research has clearly dominated the area of PMDD. Because PMDD symptoms are associated with hormonal fluctuations, cultural and psychological phenomena associated with the disorder have often been ignored in scientific research, which has resulted in a poor integration of the findings. In the field of depression and other mood disorders, multidimensional theoretical models have emerged and contributed greatly to understanding the experience of depression for an individual. In addition, exploring the interaction of biological, psychological, and social processes has expanded the range of treatment options and provided individuals who suffer from depression effective alternatives to medication. For similar reasons, an integrative approach could greatly benefit research and clinical work in the area of premenstrual mood disturbances. A two-phase approach to encompass a comprehensive biopsychosocial perspective is recommended, with the first phase emphasizing self-monitoring through charting, stress management, and dietary and

exercise programs. In addition, cognitive-behavioral coping strategies and reattribution training may help alleviate symptoms. The second phase consists of a pharmacological approach to mitigate biological aspects contributing to PMDD.

In the area of affective illness, a social zeitgeber theory of mood disturbance has been one unifying hypothesis linking biological and psychosocial models. Social zeitgebers are personal relationships, social demands, or tasks that entrain biological rhythms. Similar to the effect of light, social events are external regulators that synchronize circadian rhythms. For instance, marriage, birth of a child, divorce, and loss of a job are social events that disrupt natural meal-times, sleeping times, and times of activity, which affect the stability of biological rhythms. In individuals predisposed to affective disruption, disturbances in the biological clock may develop into a state of ongoing desynchronization as observed in major depression. Social rhythm disruptions also have been implicated in the onset of manic episodes. Ehlers and colleagues suggested that both interpersonal psychotherapy and cognitive-behavioral therapy, two empirically supported treatments for depression, address the regularity of social routine. In addition, they state that the model is likely to be influenced by personality factors, gender, social support, coping, genetic/familial loading, and past treatment experience.

Adoption of the social zeitgeber model for premenstrual mood disturbances may potentially elucidate the interaction of important psychosocial and biological etiological variables. Socially, women may be particularly prone to respond more dramatically to interpersonal conflicts because they may rely on social zeitgebers, or social relationships, more than men. Some feminist models may explain this perspective. For instance, Carol Gilligan proposed that women may view relationships in terms of interconnections and caring, and men may view relationships in terms of hierarchy and power. Developmental research has documented that girls may be more likely to engage in prosocial behavior than boys. On self-report measures, women are often more empathetic and nurturing than men. The emphasis that women may place on connection with others possibly serves as a vulnerability to a mood disturbance; interpersonal disruptions may have a greater impact on women than on men. Animal and human studies have also shown that responses to social interactions can lead to fluctuations in whole blood serotonin levels. Therefore, women may be able to regulate serotonin function by seeking appropriately rewarding social interactions; the inability to seek or receive the social interactions could lead

to further physiological dysregulation via circadian rhythm disruption and/or reduction of serotonin, manifesting as symptoms of PMDD.

At the same time, this increased need for social support may be more adaptive in the long term; women may cope with stress, such as job loss or a death, better than men. Therefore, the increased variation in mood may be more adaptive by enhancing the mechanism of homeostasis, thus protecting women against other types of long-standing illness and increasing longevity.

These correlations between behavior and neuroendocrinology have also been explored within a framework of functional hypothalamic amenorrhea. For some time, researchers have noted that psychosocial variables, such as exercise, personality traits, and environmental stress, have the potential to induce ovarian acyclicity by inhibiting the release of gonadotropin-releasing hormone (GnRH) through mediating variables, such as CRH, endogenous opioids, dopamine, and TSH. Further work in this area potentially could elucidate important somato-psychic interactions, which are key to understanding the etiology of PMDD.

The biological, psychological, and social approaches to PMDD taken independently do not take into account the more complex relationships that formulate the disorder. Practically, it may be useful to examine PMDD through a single pathway that focuses on main effects and a linear relationship. However, lack of attention to the cluster of influences and their dynamic relations may oversimplify pathways as to how individuals develop severe premenstrual disturbances. Increasingly, the biopsychosocial model of PMDD is being examined to generate a more comprehensive model. Although great strides have been made in the past decade in increasing our understanding of PMDD, we must continue to supplement current approaches with research that focuses on more complex interactions among various factors. This future direction can only be accomplished through the continued interdisciplinary effort on a multivariate, biopsychosocial approach to PMDD.

Effect of Stress on Prepulse Inhibition in Rats and Mice

Mechanism of Stress Effect on Prepulse Inhibition

Conclusion

Glossary

Prepulse inhibition (PPI)

A measure of sensorimotor gating, usually the reduction of the startle response to an intense stimulus if this is preceded by a low-intensity prestimulus.

Sensorimotor gating

A normal protective mechanism in the brain that functions to gate or filter irrelevant sensory stimulation, allowing for coherent thought.

What Is Prepulse Inhibition?

PPI is a measure of sensorimotor gating and is widely used to study information processing and attention dysfunctions. Sensorimotor gating is a normal protective mechanism in the brain that functions to gate or filter irrelevant sensory stimulation, allowing for coherent thought. Deficits in sensorimotor gating may result in stimulus overload and the misinterpretation of sensory information.

PPI of the acoustic startle response can be easily measured in several species, including rats, mice, and humans. The startle response is elicited by the presentation of short, loud acoustic stimuli (pulses or clicks) that usually induce whole-body startle responses in rats and mice and reflex eyeblink responses in humans. When the acoustic startle stimulus is preceded by a lower-intensity prestimulus (a prepulse), the subsequent behavioral response is reduced (see [Figure 1](#)). This mechanism is mediated by a well-defined neural circuit, including a short brain-stem pathway mediating the startle response and several modulating brain regions, such as the hippocampus, nucleus accumbens, and frontal cortex. PPI is deficient in a number of mental illnesses, including schizophrenia, obsessive-compulsive disorder, and attention-deficit disorder. In experimental animals, deficits in PPI can be induced by treatment with dopamine

receptor agonists, serotonin 1A and 2A receptor agonists, or NMDA receptor antagonists. Several studies have shown that deficits in humans or treated animals can be reversed by treatment with antipsychotic drugs, such as clozapine. Because of the importance of stress as a risk factor in mental illnesses, studies have addressed the effect of stress on PPI.

Clinical Correlates

A clear example of a link between stress and PPI comes from observations in patients with posttraumatic stress disorder (PTSD). There was a significant reduction of PPI when 21 Vietnam veterans with PTSD were compared to a civilian control group of 17 subjects. However, when the 21-subject group was compared to an 11-subject Vietnam veteran control group without PTSD, the difference reached only trend level. The magnitude of PPI disruption was correlated with the extent of PTSD symptoms (Mississippi scale), specifically the extent of intrusive memories and the level of arousal. Subsequent studies in other patient groups by the same authors have only partially replicated these findings. Similarly, whereas in a groups of 8- to 13-year-old children with PTSD PPI was clearly diminished, in another study of a group of 28 adolescent girls with PTSD, there were no significant differences in PPI compared to a group of 23 healthy nontraumatized girls. These discrepancies between studies could be related to the differences in the causes of PTSD in these subjects and also to parametric and methodological differences between the studies.

Many PPI studies have focused on schizophrenia. The majority of these studies have found significant disruptions of PPI in these patients, which was reversed by treatment with antipsychotic drugs. However, although stress is recognized as a risk factor in this illness, few studies have investigated stress modulation of PPI in patients with schizophrenia (see [Schizophrenia](#)).

Effect of Stress on Prepulse Inhibition in Rats and Mice

In contrast to the paucity of clinical studies on stress and PPI, several experimental animal studies have addressed this relationship. These studies can be divided according to the timing of the stress: perinatal, chronic postweaning, or acute stress.

Figure 1 Prepulse inhibition of acoustic startle in rats. a, 40-ms 115-dB startle pulse; b, response in pulse-alone trials; c, startle pulse preceded 100 ms before by a 20-ms prepulse of 12 dB above baseline; d, reduced startle responses in a prepulse–pulse trial; e, rats in the automated startle apparatus used for PPI experiments. If PPI is disrupted because of pharmacological treatment or disease, the presentation of the prepulse–pulse trial evokes responses closer to or similar to those after pulse-alone trials.

Perinatal Stress and Prepulse Inhibition

The neurodevelopmental origin of schizophrenia has led to several studies on the effect of early stress on PPI. The rationale for these studies is that an early stressful event elicits subtle changes in brain development that result in changes in behavior comparable to symptoms of schizophrenia. When rats are born, they are much less developed than humans. Thus, neonatal maternal deprivation in rats has been used to study the effects of prenatal stress factors in humans. Several neuroendocrine studies have shown prolonged alterations in responsiveness of the hypothalamic–pituitary–adrenal axis in maternally deprived rats. A single 24-h separation of rat pups from their mother also induced a disruption of PPI later in life. This disruption developed only in adulthood, and the effect was strongly dependent on the timing of the stress. Treatment with typical or atypical antipsychotic drugs could reverse the disruption of PPI in these animals. Maternal deprivation did not cause PPI disruption in all rat strains tested, suggesting an important genetic modulation of stress sensitivity and PPI. Although baseline dopamine release in the forebrain nucleus accumbens was not altered, the stimulation of dopamine release by K^+ infusion or amphetamine treatment resulted in much greater increases in dopamine levels in maternally deprived rats than in controls.

The role of maternal care has also been identified. Rat dams may be grouped according to their maternal behavior into high- and low-licking/grooming dams. The offspring of low-licking/grooming dams, which are therefore subjected to relatively low levels of maternal care, showed lower PPI than the offspring

of high-licking/grooming dams, which are subjected to relatively high levels of maternal care. This result again suggests that stress very early on in development can have long-lasting effects on behavior in general and on PPI in particular.

There are, furthermore, other studies using early stressors, such as neonatal endotoxin treatment in rats to simulate bacterial infection, or chronic stress in the pregnant dam. In many of these studies, the offspring develop deficits in PPI when reaching adulthood.

Postweaning Stress and Prepulse Inhibition

Isolation rearing in rats consists of housing the animals in single cages for a prolonged period of time. This procedure induces a significant disruption of PPI, although a comparison of different rat strains showed that this was not seen in all strains. The timing of isolation housing was also important, with the greatest disruption of PPI seen in animals that had been singly housed from weaning. Isolation rearing, and its associated behavioral perturbations, in rats has been used as a developmental animal model of schizophrenia. Indeed, disruptions of PPI in isolation-reared rats could be reversed by treatment with various antipsychotic drugs. Social isolation was associated with alterations in the release and turnover of dopamine and other neurotransmitters in different parts of the brain, which could explain the effect of antipsychotic drugs. For example, similar to maternally deprived rats, in isolation-housed rats amphetamine-induced dopamine release in the nucleus accumbens was markedly enhanced when compared to group-housed controls. A similar finding has been made in

patients with schizophrenia when compared to normal controls.

Acute Stress and Prepulse Inhibition

Only few studies have specifically addressed the effect of acute stress on PPI. It is important to note that the PPI procedure itself is mildly stressful in rodents. Acute treatment with antipsychotic drugs has been shown to result in a subtle but significant increase in PPI. This may be explained by these drugs blocking enhanced activity of dopaminergic projections and/or other neurotransmitter pathways in response to the stress of the PPI procedure. This activation can be exacerbated by acute stress shortly before the procedure, although such effects are seen only under certain conditions. For example, we have observed that the mild stress of a saline injection caused a disruption of PPI in some mice strains but not others. Similarly, injection stress caused a disruption of PPI in rats that had undergone neonatal depletion of dopamine but not in controls. Interestingly, in healthy human volunteers, mental arithmetic stress was shown to cause a disruption of P50 gating, another measure of sensory information processing. The disruption took P50 gating to the reduced level seen in patients with schizophrenia.

Mechanism of Stress Effect on Prepulse Inhibition

Peripheral Effects

Two of the hallmarks of the stress response are enhanced release from the adrenals of adrenaline and cortisol (corticosterone in rodents). In a number of studies, it has been shown that adrenalectomy does not significantly affect PPI. However, we found that the 25% disruption of PPI caused by treatment with the dopamine-releasing drug amphetamine was absent in adrenalectomized rats (Figure 2). The disruption of PPI caused by treatment with the dopamine receptor agonist apomorphine, the glutamate receptor antagonist MK-801 (Figure 2), and the serotonin-1A receptor agonist 8-OH-DPAT was not altered in adrenalectomized rats. This suggests a modulatory action of circulating factors from the adrenal, presumably corticosterone, on the brain mechanisms involved in the effect of amphetamine on PPI. These brain mechanisms probably include dopaminergic activity. This was also seen in other studies. Thus, in adrenalectomized mice, haloperidol treatment did not cause the increase in PPI seen in intact mice or adrenalectomized mice supplemented with moderate doses of corticosterone. Interestingly, the haloperidol-induced increase of PPI was also absent in mice treated with

Figure 2 Average PPI of intact and adrenalectomized (ADX) rats after treatment with saline (SAL), 0.5 mg/kg of the dopamine-releasing drug amphetamine (AMPH), 0.1 mg/kg of the dopamine receptor agonist apomorphine (APO), and 0.1 mg/kg of the N-methyl-D-aspartate receptor antagonist MK-801. All drug treatments caused a disruption of PPI compared to saline treatment, except amphetamine treatment in adrenalectomized rats, which was ineffective. * $p < 0.05$ for difference with saline treatment in the same group. Based on unpublished data from Adams and van den Buuse; for methodological details, see van den Buuse et al. (2004).

high doses of corticosterone. Similar results were seen in rats. Chronic treatment with relatively high doses of corticosterone caused a decrease of baseline PPI in rats. Apomorphine-induced disruption of PPI was markedly greater in these animals when compared to either intact controls or adrenalectomized rats (Figure 3). Taken together, these results could indicate that the dopaminergic modulation of PPI, here exposed by the action of haloperidol and of apomorphine, is dependent on certain optimal circulating levels of corticosterone. Any deviation from these optimal levels, either by adrenalectomy or treatment with high doses of the steroid, affected this mechanism.

Central Nervous System Effects

In the hypothalamus, corticotropin releasing hormone (CRH) and vasopressin are involved in the regulation of adrenocorticotrophic hormone (ACTH) release from the pituitary. The central administration of CRH caused a disruption of PPI in rats. Similarly, in transgenic mice overexpressing CRH, there was a decrease of PPI that was reversed by treatment with haloperidol and risperidone. CRH 1 receptor (CRHR1) and CRHR2 appear to play opposing roles in mediating the effect of CRH on PPI. Thus, treatment with CRHR1 and CRHR2 antagonists caused an increase or a decrease of PPI, respectively. Furthermore, the disruption of PPI caused by CRH treatment could be blocked by pretreatment with a CRHR1 antagonist. In CRHR1 knockout mice, CRH did not disrupt PPI but, rather, enhanced it. Overall, these results could indicate that CRH in the brain plays an

Figure 3 Average PPI of intact rats and of adrenalectomized rats that were implanted with either a cholesterol control pellet (ADX), a 50-mg corticosterone pellet (CORT50) or a 200-mg corticosterone pellet (CORT200). Two weeks after pellet implantation, the rats were injected with saline (SAL) or 0.1 mg/kg of the dopamine receptor agonist apomorphine (APO) and were tested for PPI. The 50–60% disruption of PPI observed in all groups was markedly enhanced (170%) in rats treated with a high dose of corticosterone. * $p < 0.05$ for difference with saline-treatment in the same group. Based on unpublished results from Adams and van den Buuse; for methodological details, see van den Buuse et al. (2004).

important role in the effects of stress on sensorimotor gating. Conversely, drugs acting on CRH receptors could be relevant in reversing PPI deficits in patients with PTSD or schizophrenia.

There is limited information on the role of vasopressin in PPI. Vasopressin-deficient Brattleboro rats display disruptions of PPI that can be reversed by chronic, but not acute, treatment with haloperidol. Also vasopressin V1b receptor knockout mice show a disruption of PPI. Chronic treatment with the atypical antipsychotic drugs, risperidone and clozapine (but not the typical antipsychotic, haloperidol) reversed this PPI disruption. The authors noted decreased extracellular levels of dopamine in the frontal cortex of these animals; however, the activity of the hypothalamic-pituitary-adrenal axis was not investigated.

Conclusion

Studies on the modulation of PPI by stress and peptides involved in the stress response provide

important insights into the role of stress in the symptoms of illnesses such as PTSD and schizophrenia. The effect of stress on PPI is mediated by circulating factors, such as corticosteroids, or central factors, such as CRH.

effects consist of neuropsychological complaints regarding cognitive functioning and fine visuomotor tempo and coordination.

Introduction

Humans Working under High Pressure

Humans Working under Low Pressure

Concluding Remarks

Glossary

<i>Acute mountain sickness (AMS)</i>	A high-altitude illness, which can be classified as normal or malignant AMS. Malignant AMS includes features of both pulmonary and cerebral edema.
<i>Chronic mountain sickness (CMS)</i>	A high-altitude illness whose symptoms are vague neuropsychological complaints, including headache, dizziness, fatigue, and difficulty concentrating.
<i>High-pressure nervous syndrome</i>	Behavioral disturbances after being at depths greater than 150 m. Central nervous system manifestations include tremor, dizziness, nausea, and electroencephalogram changes. It becomes more severe with increasing depth and during fast rates of compression.
<i>Hypoxia</i>	Lack of oxygen that results from, at normal pressure, a reduction of pO_2 and, at high altitude, the reduction in atmospheric pressure. Central nervous system manifestations differ between acute hypoxia (seconds to 1–2 h) and chronic hypoxia (hours to years).
<i>Nitrogen narcosis</i>	An illness from breathing compressed air at depths deeper than 20 m; characterized by euphoria, impaired cognitive functioning, and impaired neuromuscular coordination.
<i>Oxygen toxicity</i>	An illness that increases progressively with the increase of inspired pO_2 and with greater duration of exposure; central nervous system manifestations range from localized muscle twitching to grand mal seizures.
<i>Residual effects</i>	Residual impairment of central nervous system functioning following the return to normal pressure from deep depths and from high altitudes. For both high- and low-pressure conditions, the residual

Introduction

What Constitutes Extreme High- and Low-Pressure Conditions for Humans?

As we have throughout the centuries, today humans go into the sea for food, military operations, sport, treasure-hunting, and exploration. The earliest indications of breath-hold diving and the first techniques used by humans at work in the sea are from an archaeological dig in Mesopotamia dating from 4500 BC and from Aristotle, who in the fourth century BC mentioned a type of diving machine. The historical stages in the development of diving are:

1. Breath-hold diving (also called free diving)
2. Diving bells
3. Surface-supported or helmet diving (also called hard-hat diving)
4. Self-contained underwater breathing apparatus (scuba diving)
5. Saturation diving

Diving physiologists had, by the late 1950s, made great strides toward understanding and managing some of the principal hazards that beset divers in their progress toward the depths. These hazards included oxygen toxicity, the narcotic effects of inert gases used as oxygen diluents in high-pressure environments, and the mechanical effects of dense atmospheres on respiratory work and the effectiveness of ventilation.

When oil and gas exploration started in the North Sea in the 1960s, diving became important for the maintenance, inspection, and repair of subsea installations. Therefore, the saturation diving technique was developed further, and diving to depths between 50 and 180 msw (meters of seawater) became a standard procedure. In parallel with this offshore diving, experimental studies on diving down to a maximum of 850 msw were conducted in the United States, Europe, and Japan. This research led to the observation of the high-pressure nervous syndrome (HPNS), a syndrome consisting of tremors, dizziness and nausea, electrophysiological changes, and impaired performance.

Humans, however, expose themselves to more than just extremely high pressures. For centuries, humans

have attempted to climb higher and higher, and scientists have been astonished repeatedly by mountaineers' ability to ascend higher than their confident predictions. Whereas the central nervous system (CNS) problems from diving are due to oxygen toxicity, inert gas narcosis, and HPNS, the CNS problems of extreme altitude are due to hypoxia (because there is reduction in atmospheric, and hence oxygen, pressure with increases in altitude) and cold (because of the temperature decrease with altitude and wind chill).

One of the earliest European reports of the problems of high altitude was given by the Greeks who, during their yearly ceremonial visit to the summit of Mountain Olympus (2911 m), were not able to survive unless they applied moist sponges to their noses (possibly soaked in vinegar). The first documented description of mountain sickness comes from Chinese sources in 32–37 BC. It has been suggested that the occurrence of mountain sickness and its complications may have been taken by the Chinese as a sign for them not to transgress their natural boundaries.

In the late nineteenth and early twentieth centuries, there was increasing scientific and medical interest in both the oxygen transport system and altitude adaptation, and many discoveries were made. Viault recorded the best-known physiological response to high altitude – an increase in the number of red blood cells. The tempo of Himalayan exploration accelerated during this period, and in 1892 while on Pioneer Peak (7000 m), Conway described the debilitating effects of long periods at high altitude. In 1953, the first ascent of Mt. Everest (8848 m) was conducted by Hillary and Tensing. However, they used supplementary oxygen. In 1978, Messner and Habeler made the first ascent of Mt. Everest without supplementary oxygen, and in 1987 the same was done in the winter (December) by Sherpa Ang Rita.

What Constitutes the Physical Characteristics of These Conditions?

Diving Awareness of the natural laws covering diving, and the results of disobedience, has fostered the development of the systems and techniques that allow humans to dive safely to increasingly greater depths. The laws are the ideal gas law (behavior of gases at low pressures), Boyle's law (volume is inversely proportional to pressure), Charles's law (volume is directly proportional to temperature), real gas law (behavior of gases at high pressures), Dalton's law (law of additive partial pressures), Graham's law (diffusion rate is proportional to molecular rate), Amagat's law (law of additive partial volumes), thermal laws (specific heat, conduction and convection, and heat transfer), acoustical laws (conduction, diffraction, and the speed

of sound), density laws (Archimedes's principle), and optical laws (curvature of light and absorption of color). A direct line can be drawn from any existing diving technique to at least one of these fundamental laws.

When people dive down to a certain depth, a compression profile is followed. For each 10 msw of depth, the pressure increases 1 atm absolute (ATA). Especially in the 1970s, surface-oriented diving with a wet diving bell was common practice. Two men descended, for example, in the bell to approximately 100 msw (11 ATA). The compression rate was normally in the range of 30 msw min⁻¹ (3 ATA min⁻¹). The average time at maximum pressure was less than 30 min, and the tasks involved light or moderate effort. Only one diver exited to the work site while the other monitored his or her activity and stood by to assist.

Because the time required to come back to surface (decompress) is often longer than the time spent on the bottom, the ratio of diver work time to decompression time is not always a favorable one (if a diver decompresses too fast, he may get the bends, that is, gas bubbles in the skin, joints, spinal cord, or bloodstream).

The price that a diver must pay for staying deeper and longer led to the development of saturation diving. First accomplished in 1938, this diving technique was developed further in parallel with the oil and gas exploration in the North Sea. If a team of divers are to work at 150 msw (16 ATA), they compress to 16 ATA in a living chamber at a diving platform or vessel and stay at that pressure for 10 days. Pairs of divers then enter a dry diving bell, which is lowered to the work site at 150 msw. The bell stays at that depth for up to 8 h, and one diver at a time works in the water for half the period. After the 8-h period, the bell is taken up to surface and connected to the living chamber where the divers eat, relax, and sleep (all the time under the same pressure). After 10 days, they start decompression to surface pressure, which takes several days.

High altitudes In 1878, it was known already that most of the deleterious effects of high altitude in humans were caused by hypoxia, a direct result of the reduction in atmospheric pressure. However, there is still confusion about the relationship between barometric pressure and altitude, particularly at extreme heights. For example, the barometric pressure at the summit of Mt. Everest is considerably higher than that predicted by the standard pressure–altitude tables used in aviation.

Although most of the high-altitude effects are due to hypoxia, additional deterioration results from cold, dehydration, and solar and ionizing radiation.

Most of these additional hazards, however, can be avoided by using proper clothing or shelter. Only hypoxia is unavoidable unless supplementary oxygen is available. Low barometric pressure itself has no physiological consequences unless the decompression is rapid. For example, when a window fails in an aircraft, an explosive decompression can occur; and, just as in diving, rapid decompression causes barotraumas as a result of the very rapid enlargement of airspaces within the body, especially in the lungs and middle ear cavity.

Humans Working under High Pressure

Working Conditions (Types of Diving)

Helmet diving The first major breakthrough in helmet diving was the invention of an open diving dress in 1819 by Siebe, a waist-length jacket, a metal helmet, and air under pressure supplied from the surface to the helmet. Siebe later modified his open dress to the closed type, retaining the helmet and force pump and enclosing divers in a continuous airtight dress. Air was vented by a valve, the basis for modern hard-hat diving gear.

As advances were made in helmet diving, divers gained more air, more protection, and more mobility, but it was not until the development of self-contained underwater breathing apparatus (scuba) gear that they were afforded the freedom that breath-hold divers had to move about, coupled with an air supply that enabled them to stay down longer than free divers.

Scuba diving The Cousteau–Gagnan valve (aqua lung, presented in 1943) is the basis for modern open-circuit scuba gear. Open-circuit breathing gear usually contains compressed air as a breathing mix. It has a demand regulator, which provides air when the diver inhales, and the air is vented into the water on exhalation. To conserve the breathing mix and extend the time at depth, closed-circuit and semiclosed rebreathers have been developed.

A closed-circuit apparatus can employ pure oxygen or a mixed gas with oxygen and a diluent gas such as nitrogen or helium. The risks inherent in breathing pure oxygen, primarily oxygen toxicity, limit the operating depths to approximately 10 msw or 18 msw resting.

When divers go deeper than 30 msw on air, dangerous signs and symptoms of euphoria, intoxication, and narcosis occur. The first inference that the nitrogen constituent of compressed air is responsible for this narcosis was made by Behnke and colleagues in 1935. They concluded that compressed air at depths

deeper than 20 msw exerts a narcosis characterized by “euphoria, retardation of the higher mental processes, and impaired neuromuscular coordination” (Behnke et al. 1935). The signs and symptoms of the narcosis are similar to those due to drinking alcohol, hypoxia, and the early stages of anesthesia. Exposure to depths greater than 90 msw may also result in loss of consciousness.

Saturation diving The use of saturation diving in a commercial application was, in fact, suggested by Behnke as early as 1942. He noted that frequent decompressions were “not only potentially dangerous, but highly uneconomical. It would appear advisable therefore to keep men at work on a job continually under pressure” (Behnke 1942).

Although the first saturation dives were made using air, this method has never been used for diving at a depth less than 40 msw. For diving deeper, however, this has been the main diving technique since the early 1980s. What they initially had to do, however, was remove the nitrogen (which would lead to narcosis) and use helium instead. The breathing gas in saturation diving is therefore called heliox (helium and oxygen).

Modern-day saturation diving platforms in the North Sea have greatly extended diving capabilities. Up to 28 people can be in saturation, making excursions to different depths with two bells. Compression to depths greater than 150 msw, however, produces the signs and symptoms of high-pressure nervous syndrome (HPNS). The syndrome includes tremor in the hands and arms, electroencephalograph (EEG) changes, dizziness, nausea, and vomiting. At depths greater than 300 msw, lapses of consciousness may occur. The symptoms of HPNS become more severe with increasing depth and during fast rates of compression.

Effects on the Central Nervous System

As already indicated, several CNS reactions may occur when divers are exposed to this high-pressure environment. The stress reaction in the individual diver, however, is a product of a combination of factors, psychological and physiological, and is often a synergistic effect. This section focuses on the following six factors, which both alone and in combination can lead to severe stress and, in some cases, a fatal outcome in diving: (1) anxiety and panic, (2) oxygen toxicity, (3) nitrogen narcosis, (4) HPNS, (5) isolation and confinement, and (6) residual effects.

Anxiety and panic Stress during diving is probably the central problem causing the accidents and resulting injuries and fatalities that occur in sport divers.

Most diving-accident researchers implicate panic, as a response to stress, as the major cause of diving fatalities. The skills learned in training, such as the careful use of equipment and the techniques of coping with accidents, appear to be lost when divers panic. Therefore, it is important for divers, especially sports divers, to understand stress and to learn to handle stress.

Divers' use of defensive reactions to a threat also lead to inadequate performance under stress, and decrements in both defense mechanisms and performance relate to endocrine stress reaction. The first study demonstrating that perceptual defense mechanisms, as tested by the defense mechanism test (DMT), predicted individual reactions to dangerous situations was on attack divers. Three groups of divers ($N = 29$, 20, and 29) were tested with DMT, and the protocol was coded, rated, and ranked independently by three raters. All three raters' predictions, based exclusively on the DMT results, correlated significantly with the pass/fail criteria at the school.

In later studies in which more specific performance criteria were used, the same relationships were found. In a study of 45 navy divers, the individual score on defense mechanisms correlated significantly with the reduction in reasoning capacity at 60 msw. In a study of 29 navy divers, the same relationship between defense mechanisms and mental performance was found. In addition, the factor pattern of the endocrine postdive measures showed cortisol, catecholamine, and testosterone factors. There was a correlation between the cortisol factor and both defense pattern and performance decrement, confirming previous studies from other high-risk environments (parachutists).

Oxygen toxicity The greater application of hyperoxygenation both in therapy and in diving since the early 1970s has led to a better understanding of the universal dependence of vital biological processes on the cellular antioxidant defense mechanisms that have evolved as an adaptation to Earth's atmospheric oxygen tension. It is now apparent that the same oxygen pressures required to sustain life cause lethal oxygen poisoning in the absence of these mechanisms.

The severity of oxygen poisoning increases progressively with the increase in the inspired partial pressure of oxygen and greater duration of exposure. At sufficient pressure and exposure duration (i.e., an attack diver breathing pure oxygen at too great a depth), oxygen initially causes functional impairment and ultimately causes the chemical destruction of any living cell.

Donald exposed divers to oxygen pressures of 3 ATA or higher until CNS effects were experienced.

Unfortunately, the sequence of progression did not consistently include minor symptoms before the onset of convulsions. Even when preconvulsive aura was experienced, it was sometimes followed so rapidly by seizures that it had little practical value as a warning. An enormous variation in oxygen tolerance was found among divers exposed to the same conditions. Attempts to correlate CNS oxygen tolerance with factors such as age, weight, physical fitness, smoking, alcohol ingestion, psychological stability, or personality traits were all unsuccessful. Even in the same diver, there was considerable variability in oxygen tolerance from day to day. The conclusion was that variability in oxygen tolerance from day to day within the same subject was as great as between subjects.

The seizures caused by oxygen toxicity are essentially the same as those occurring in grand mal epilepsy. They can be preceded by an aura or by a sequence of premonitory sensations, or they can occur suddenly. In contrast to the cerebral hypoxia that occurs during an epileptic seizure, brain hyperoxygenation is maintained during an oxygen convulsion by a high alveolar partial pressure of oxygen in conjunction with marked hypercapnia and increased cerebral blood flow. Biochemical studies on free radicals under hyperoxic conditions have shown, however, that extracellular hyperoxia leads to cellular hypoxia through free-radical mechanisms.

However, it is not only the use of pure oxygen in diving that can lead to serious CNS problems. Ongoing research has shown that there is probably a synergistic effect between oxygen (in heliox with a partial pressure of O_2 of only 0.6 ATA) and high pressure when people dive to extreme depths (>300 msw), contributing to the explanation of CNS-related symptoms and signs (e.g., HPNS) that are observed.

In a series of experiments, the effects of various partial pressures of oxygen (0.2, 0.4, and 0.6 ATA) in the heliox breathing gas on HPNS were studied in rats. Rats were exposed to 91 ATA, equivalent to approximately 45 ATA for humans. The results showed that HPNS symptoms were reduced significantly with a lowered oxygen partial pressure. Follow-up studies on the effects of hyperbaric oxygen ($>95\%$) on neuronal transmission in the perforant path/dentate area of hippocampal formation showed that epileptic seizure activity produces long-term changes in synaptic excitability in granular cells of the dentate area.

The inhibition of nitric oxide (NO) production has been reported to delay the onset of hyperbaric oxygen-induced epileptic seizures in mice and in rats. The mechanism(s) behind this protective effect is still equivocal. It has been suggested that NO is

involved in the regulation of blood flow and arterial pressure, as a transmitter in peripheral nerves, and as an intercellular or, rather, transcellular transmitter between CNS neurons. The protective effect of inhibiting NO production could, therefore, be due to changes in cerebral blood flow, neuronal activity, or both.

Nitrogen narcosis All divers know that diving deeper than 30 msw on air can lead to dangerous symptoms and signs of euphoria, intoxication, and narcosis. One of the first reports of nitrogen narcosis was given by a Frenchman in 1835. Around the turn of the twentieth century, it was reported by several others in tunnel workers breathing air at 46 m. However, as mentioned previously, Behnke and co-workers were the first to claim that nitrogen was the agent responsible for the narcosis (Behnke 1942).

As might be expected, there is a wide variation in individual susceptibility. Whereas one diver becomes narcotic at pressures as high as 50 msw, another is affected quite severely at only 30 msw. In this connection, Cousteau claimed that emotionally stable individuals are usually affected to a smaller extent than less stable subjects. This was confirmed later in experimental studies by Værnes in which divers sat in a pressure chamber taking cognitive tests on paper and performing no other physical activity.

In both studies, a significant reduction in long-term memory (LTM) was found. When information input was done predive and recall at 60 msw, the mean reduction in LTM was 31.2%. When input was done at 60 msw and recall later at the surface, LTM impairment was even worse (45.6%). (The control situation was both input and recall at the surface in the same chamber with the same duration between input and recall.) Memory impairment was obviously a major effect of nitrogen narcosis. As reported earlier, some divers also had a reduction in reasoning, although the average reduction was not significant. However, for reasoning impairment, in both studies there was a significant correlation with the degree of defensive reaction pattern as defined by DMT, and in the second study, it also correlated with the degree of cortisol activation.

High-pressure nervous syndrome Compression in a heliox atmosphere induces a number of behavioral disturbances at depths greater than 150 msw (16 ATA). These disturbances were described by Bennett as nausea, vertigo, and tremor during rapid compression to 180 msw, and he attributed them to the helium (i.e., helium tremor). Brauer and colleagues and Fructus and colleagues described a number of symptoms occurring during simulated dives between 300 and

365 msw. The symptoms have been termed the high-pressure nervous syndrome (HPNS) and include tremor in the hands and arms, increased slow-wave activity (2–7 Hz) and depression of α waves (8–13 Hz) in the EEG, dizziness, nausea, and vomiting. The syndrome was replicated by Bennett and Towse during a dive to 457 msw, and it has been demonstrated that lapses of consciousness may occur at depths greater than 300 msw. The symptoms of HPNS become more severe with increasing depth and during fast rates of compression.

Various methods have been used to ameliorate the signs and symptoms of HPNS, including the selection of less sensitive divers, the use of excursions from a shallow saturation exposure, slow exponential compression with stops for adaptation, and the use of narcotics to antagonize the effects of HPNS. Studies of these methods have shown that the speed of compression correlates with the extent and intensity of the various symptoms. In particular, a slow compression interrupted by holding stages has been shown to reduce HPNS considerably.

A major problem in evaluating the effects of HPNS by manipulating the compression conditions or selecting less sensitive divers is the individual variation in the reaction pattern. Whereas one diver may show a normal EEG but significant tremor followed by impaired motor performance, another diver may show normal motor functions but significant EEG changes accompanied by impaired cognitive performance. To study these different responses, it is recommended that a relatively comprehensive battery of tests be used for evaluating a compression profile. The validity of such a battery of tests can be related not only to fitness at depth but also to the temporal aftereffects that have been observed in deep diving.

Therefore, a compression profile with holding stages and a slower compression rate at deeper depth has been developed for operational diving to 180 msw and deeper in the North Sea. In a series of simulated dives to 360 msw, including a total of 18 divers, the proposed profile was evaluated. HPNS testing revealed only mild effects of the compression. Only three divers had impairments of more than 2 standard deviations in peripheral motor function. Memory was impaired periodically in two divers. Their tremor had minimal effects on their performance. In only 1 of the 18 divers had a marked EEG change followed by cognitive impairment. The results confirmed that using a compression profile with rates decreasing progressively with increasing depth, and with several intermediate stops, provides fit divers at depth.

This profile was later used in the tie-in operation at 220 msw at, by then, the world's largest oil platform (Gullfaks C) in 1989. A total of 52 divers took part in

the operation and all were tested with a field battery of HPNS tests at pressure before being allowed to start work in the water. No dives were aborted due to HPNS, and only 1 out of the 52 divers had to have an extended observation period in the living chamber (6 h) before being allowed to start the in-water operation. Although made even more conservative through two revisions, this original profile is the standard profile today for all diving in the Norwegian sector of the North Sea deeper than 180 msw.

Several studies have suggested that cerebral monoamines may be involved in the occurrence of some HPNS symptoms. Some studies suggested that dopamine (DA) counters the convulsive activity induced by pressure. Nevertheless, others did not find significant changes in the concentration or kinetics of DA analyzed in the brain homogenates of animals after exposure to pressure.

More recent studies in free-moving rats using microdialysis confirmed that the pressure induced striatal increase and implicated D1, D2, and NMDA receptors in this change. Recent works performed on GABA_A or GABA_B receptors using agonists (muscimol or baclofen) injected focally in the substantia nigra pars reticulata (SNr) or substantia nigra pars compacta (SNc) implicated these receptors in the striatal DA release and showed that helium pressure inhibits the activity of GABA neurotransmission at the level of substantia nigra, which induces a DA change.

Microdialysis studies indicated that the helium pressure induces an increase of serotonin (5-HT) in the striatum, which can explain the activation of these receptors. At the level of nucleus accumbens, the use of 5-HT_{2C} receptor agonists indicates that this receptor plays a crucial role in the development of locomotor activity (LMA) and in the pressure-induced increase in DA accumbens release. In contrast, the administration of 5-HT_{2A} receptor antagonists had no effect on LMA and DA increase, but it reduced myoclonia. These results suggest that helium pressure may simultaneously induce an increase in 5-HT transmission at the level of 5-HT_{2A} receptors and a decrease in 5-HT transmission at the level of 5-HT_{2C} receptors.

These studies are some examples of the several neuropharmacological and neurochemical findings that have increased our information on the origin and mechanisms of HPNS. In summary, it can be stated that helium pressure acts specifically on some neurotransmissions, on some neurochemical interactions between the systems and the structures, and on some receptors or on their synthesis. It is evident, however, that more work remains to be done to increase our understanding of the effect of pressure on the nervous system.

Isolation and confinement In addition to these pressure- and gas-related effects of deep diving on the CNS, studies have found that isolation and confinement themselves can have an effect. Although the stimulus-deprivation studies performed in the 1950s showed that the CNS needs stimulus variation, these extreme experiments seemed to be a long way from living in a small chamber (be it a saturation diving complex or a space station) for several weeks.

How has it been possible to evaluate this effect? Did someone pay to lock up test subjects inside a pressure chamber at normal atmospheric pressure for weeks? American, Russian, and European space agencies have used diving saturation chambers to evaluate the effects of long-term isolation and confinement in conjunction with preparing astronauts for space station Mir and the future international space station Alpha. Using these space-related experiments, it is possible to analyze the effects of isolation that a diver is exposed to during deep, long-duration (>30 days) dives. Three such experiments performed by the European Space Agency (ESA) are described next.

The Long-Term Programme Office (LTPO) of the Directorate of Space Station and Microgravity (D/SSM) at ESA carried out studies on the psychological and physiological aspects of long-duration human spaceflight in multinational crews under conditions of isolation and confinement in diving saturation chambers. LTPO first performed an experimental test with a crew of six men for 28 days (ISEMSI-90) at the Norwegian Underwater Technology Center (NUTEC) in Bergen, Norway, and then performed a second one with a crew of four (three men, one woman) for 60 days (EXEMSI-92) at Deutsche Zentrum für Luft-und Raumfahrt (DLR) in Cologne, Germany. In 1994, ESA was planning the EUROMIR-95 long-duration flight (135 days) of a European astronaut on board the Russian orbital station Mir. In order to perform detailed investigations on the human-related aspects in such a long-duration isolation, ESA organized a ground simulation, the Human Behavior Study (HUBES), for which the chamber facility at the Institute for Biomedical Problems (IBMP) in Moscow was set up like a small space station.

Cognitive fatigue and subjective health symptoms occurred in all three studies. On performance, an increase in decision time and an increase in the number of errors were found in several of the experiments. For the physiological studies, HUBES confirmed the earlier findings of the ISEMSI-90 and EXEMSI-92 tests, showing weekly rhythms, individual rhythms, and overall phases as in the group psychology studies. It was therefore concluded that for long-duration

dives (and spaceflights) experimenters will have to take into account the individual biological patterns of the subjects. If this is done, the outcome of the experiments will be more predictable and the comparison of data between the subjects will become easier.

These three ESA experiments have therefore shown, among other things, that the timing of individual experiments is critical when parameters are involved that are strongly under endocrinological control, such as those of the salt-water homeostasis, and therefore display rhythmic patterns.

Residual effects As in high-altitude medicine, researchers in diving medicine have vigorously debated the possibility of residual impairment of CNS function following the subjects' return to normal pressure. Several deep saturation dives performed between 1968 and 1989 showed temporary CNS changes immediately after the dives. Given these CNS changes, observed both immediately postdive and during deep saturation dives, an important question was whether chronic CNS effects could develop after single or repeated exposures, as in the previous findings on diving accidents.

The neuropsychological status of saturation divers was assessed before and after 300–500 msw dives (deep saturation diving, DSD group, $N = 64$) and before and after 3.5 years of ordinary saturation diving (SD group, $N = 32$). The average baseline results showed divers to be slightly superior to the nondiving controls. Mild-to-moderate neuropsychological changes ($>10\%$ impairment) were found in measures of tremor, spatial memory, vigilance, and autonomic reactivity in 20% of the divers after deep dives (DSD group). One year postdive, no recovery was observed except for a vigilance test. In the SD group, 20% of the divers showed $>10\%$ impairment after 3.5 years of ordinary saturation diving. A significant reduction in autonomic reactivity was also found, and there was a relationship between low autonomic reactivity before saturation diving and the number of impairments that were $>10\%$. For the whole group (DSD + SD divers), negative correlations were found between saturation experience and results on memory and complex visuomotor tests. The number of years of diving from the first to last examination correlated positively with the number of impairments that were $>10\%$ and with a reduction in autonomic reactivity. No similar correlations were found at dive variables after approximately 3 years of air diving.

The mild-to-moderate changes seen in some divers, therefore, seem to be the effects of saturation diving. Because one deep dive may cause an effect similar to

the effects of 3.5 years of ordinary saturation diving, there is reason to believe that repeated deep diving may lead to more pronounced neuropsychological impairment.

Such mild-to-moderate changes in some divers indicate the start of a pathological process on the subcortical level (mild encephalopathy) such as a decrease in memory and vigilance, low autonomic reactivity, and increased tremor, but the underlying mechanisms are unclear. The degree of individual reaction and the variation in symptomatology indicate that the mechanisms for both the temporal and the subtle permanent changes after saturation diving are very complex. Individual factors, additive factors, and synergistic mechanisms may be involved.

Several international studies followed the publication of the Norwegian study and were reviewed by Dutka. In his review, Dutka states that divers who have had decompression sickness can develop long-term health effects, although there are conflicting results among deep-sea divers with no history of decompression sickness. His conclusion is in conflict with the follow-up study on North Sea divers presented in 2003 by Troland. In this study, the results seem even more convincing, supporting the statement from an international consensus conference that said: "There is evidence that changes in bone, the central nervous system and the lung can be demonstrated in some divers who have not experienced a diving accident or other established environmental hazards. The changes are in most cases minor and do not influence the divers quality of health. However, the changes are of a nature that may influence the diver's future health (Hope et al. 1994)."

Humans Working under Low Pressure

Conditions

Human responses to hypoxia are complex and depend, among other things, on the severity of the hypoxia and the rate at which it is imposed. Severe sudden hypoxia experienced by aviators when cabin pressure is lost at a high altitude produces an entirely different result than that experienced by a climber who reaches the same altitude after weeks of acclimatization. Furthermore, people with a lifelong exposure to high altitudes develop further changes in response to hypoxia compared with even acclimatized lowlanders. Adaptations may also occur after a species has lived at high altitudes for generations due to the selection of genes advantageous to life in the hypoxic environment.

Generally, hypoxic conditions can be divided into four categories: (1) acute hypoxia (from seconds to

1–2 h), (2) chronic hypoxia (from hours to years, i.e., subjects in chamber experiments, mountaineers, workers in high-altitude mining towns, sea-level residents who go to high altitudes), (3) lifelong hypoxia (i.e., high-altitude residents who were born, bred, and live at high altitudes), and (4) species that have lived at altitude for generations.

Effects on the Central Nervous System

People who go to high altitudes often have changes in neuropsychological function, including memory, mood change, and special senses such as vision. This has been observed both in lowlanders staying at high altitudes for some time and in high-altitude natives. There is also mounting evidence that there may be persistent CNS defects on return to sea level after periods of severe hypoxia at high altitude. This is analogous to the indications of permanent CNS after-effects in some divers after deep diving.

Because an increasing number of climbers choose to climb at great altitudes without supplementary oxygen, these findings are of special interest. The increase in morbidity and mortality during such expeditions and the occurrence of irrational decisions made by severely hypoxic climbers have also led to serious concern from medical and operational points of view.

Acute hypoxia At modest altitude (>1500 m), breathlessness may be felt on exertion and some rise in heart rate may be noticed, but the main effect is on the CNS. Night vision is impaired at altitudes as low as 1500 m. The tingling of the fingers and mouth may be noticed at 4000–5000 m. However, although now definitely hypoxic, climbers have very little subjective prewarning. Some people may become unconscious above 5000 m, whereas most become unconscious at above 7000 m. In response to an acute exposure to Mt. Everest's altitude (8848 m), unacclimatized subjects remain conscious for only approximately 2 min.

Within the brain, the hippocampus, white matter, superior colliculus, and lateral geniculates appear particularly sensitive to levels of oxygen. Brain lactate levels increase during the early stages. The brain tissue concentrations of ATP, ADP, and AMP apparently remain close to normal even during severe hypoxia. In animal studies in which the arterial partial pressure of oxygen is reduced gradually (from 80 to 20 mmHg), the subjects' EEG amplitude initially increases slightly and then slow waves and spikes appear. Subsequently, the slow waves decrease in amplitude and then disappear; the small spikes become sporadic, and finally the EEG flattens. This initial activation followed by depression may be due to hypoxic effects

on the reticular activating system. Visually evoked potentials are increased initially and are then abolished as the level of oxygen is reduced. The brain-stem auditory response is abolished by hypoxia.

The effects of hypoxemia and hypocapnia at high altitude have opposing effects on the cerebral circulation. There have not, however, been systematic studies of the cerebral blood flow at various altitudes, partly because of the difficulties of measurement.

Chronic hypoxia at moderate altitudes It has been important to study the effects of mild hypoxia on the performance of aircrews, who are required to maintain peak performance for hours while performing monotonous tasks under hypobaric conditions. There is a general agreement that CNS function is impaired at altitudes over approximately 4500 m; however, what is the lowest altitude at which minor, but operational, significant alterations in CNS occur? This question arises frequently in the aviation industry because it is important in selecting the cabin pressure of commercial aircraft.

Earlier studies showed that performance declines as the time devoted to vigilance tasks increases. Studies on the effects of hypoxia on vigilance performance have produced contradictory evidence. Impairment in performance was found at altitudes as low as 4000 m and carboxyhemoglobin (HbCO) levels of 1.8%. Other studies found no similar effects at 3500 m and at HbCO as high as 8.4%.

Further studies of people performing tasks at high terrestrial elevations have, however, demonstrated that impairment of a wide range of tasks occurs and that this correlates with the degree of hypoxia. In addition, animal performance in tests of maze performance, visual discrimination, or nondiscriminated avoidance are affected adversely by exposure to low oxygen tension. These changes are qualitatively similar to the behavior noted in rats when levels of brain biogenic amines, norepinephrine and DA, are reduced by pharmacological agents. Hypoxia also affects brain norepinephrine in rats. Exposure to 5 or 10% O₂ for 1 h resulted in a 23% decrease of this amine.

The variability in the response to hypobaric exposures, both within and between individuals, has been emphasized in relation to the symptoms and signs of hypoxia. Some proportion of the variation may be due to the differences in the respiratory responses to the hypoxia, causing significant temporal and individual differences in the tensions of oxygen and carbon dioxide in the arterial blood. Furthermore, the degree of cerebral vasoconstriction also causes a proportion of this variation.

Performing learned psychomotor tasks is unimpaired to at least 3000 m. Long- and short-term

memory, arithmetic, and conceptual reasoning tests are also unaffected below 3000 m. Previously, it was assumed that this degree of hypoxia did not produce any effects on human performance. However, breathing air at 2500 m causes a significant increase in the time required to achieve optimum performance on a novel task. The delayed learning is probably due to the retardation of some oxidative processes within the brain rather than to interference with oxidative phosphorylation, which hardly can be affected because the oxygen tension of the cerebral venous blood falls 2–4 mmHg during an ascent from ground level to 2500 m. The impairment of learning increases markedly at altitudes above 3704 m (12 000 feet).

A study by Værnes and colleagues was designed to examine the effects of a prolonged exposure to mild hypoxia on performance and endocrine reactivity. An altitude of 3048 m (10 000 feet) was simulated in an altitude chamber for 6.5 h. The study was initiated after reports of some cases of headache, dizziness, visual disturbances, and subjective feeling of performance decrement by an aircrew on a maritime surveillance aircraft during a trans-Atlantic flight with a cabin altitude of 3048 m. The aim of the study was to determine whether these symptoms were the effects of general stress, mild hypoxia, or a combination of both.

Performance tests indicated significant effects of hypoxia. In contrast to earlier studies on the relationship of hypoxia and performance, no relationship between impaired performance and duration of exposure to hypoxia was found. Repeated testing throughout exposure indicated stable individual reactions. The endocrine variables did not support the hypothesis that activation or stress caused the impairment observed. In addition to impaired neuropsychological test performance and impaired task performance, subjects reported headache, weakness, and some dizziness. Comparisons of the various tests confirmed the previous results showing that mild hypoxia yields varying degrees of impairment on different cognitive functions.

Changes that take place over a period of hours to months at altitude, termed acclimatization, occur in different systems of the body and have a different time course. In some cases, they involve a biphasic response (i.e., the heart rate shows a rise within minutes, followed by a fall over weeks at altitude). The best-known response is the increase in hemoglobin concentration due to the rapid decrease in plasma volume followed by a much slower increase in red cell mass.

Adaptation takes place over decades or is the result of being born and bred in a mountain environment. No definite examples of CNS-related adaptation

have, however, been demonstrated in humans, but examples include an increase in the number of branches leaving the main coronary trunks and the blunting of the hypoxic ventilatory response.

The observed deterioration in the mental and physical conditions of humans as a result of prolonged stay at altitude is termed high-altitude deterioration. The term was first used by members of the early Everest expeditions. High-altitude deterioration, in the absence of dehydration, hypothermia, exhaustion, and/or starvation, is characterized by poor appetite, weight loss, lethargy, slow recovery from fatigue, an increasing lack of will power to start new tasks, and irritability. The mechanisms underlying this deterioration are unknown, but it is quite obvious that the effect of chronic severe hypoxia on the CNS plays an important part.

Chronic hypoxia at high altitudes Both simple and more complex psychological functions are impaired significantly at high altitudes (>6000 m), including arithmetical tests, writing ability, and the appearance and disappearance of afterimages following exposure of the eye to bright light. Increased memory errors, errors in perseverance, and reductions in auditory threshold and words apprehended are also observed. In a series of now-classic studies, measurements of sensory and motor functions were made at several altitudes. It was found that impairment was not significant below 5300 m. Subjects with longer periods of acclimatization appeared to suffer less deterioration.

The general findings from several such performance studies showed consistently that there is an increased distractibility and lethargy that tend to reduce the subjects' ability to concentrate. These results are consistent with the impression reported by many people who have worked at high altitude, namely that thought processes are slowed but that, if one concentrates hard enough, accurate procedures can be carried out.

Changes in the human EEG have been observed at high altitudes (5500 m). Ryn reported both an α -wave frequency decrease and paroxysmal and focal pathology. In general, there were abnormalities in 11 out of 30 climbers. Partly the same pattern was later found by Zhongyuan and colleagues at altitudes above 5000 m. However, the changes were less than those observed during acute hypoxia at the same altitude simulated in a pressure chamber prior to the expedition. A general finding was that members of the expedition who tolerated the acute hypoxia well tended to show fewer EEG changes on the mountain.

Recent studies on altitude exposure above 6000 m showed an increased susceptibility to hallucinatory

experiences in mountaineers who refused to use supplementary oxygen. The autonomic nervous system seems to play a crucial role in the short-term adjustment to hypoxia. There is increased sympatho-adrenal activity associated with decreased parasympathetic tone, and vasomotor depression due to central hypoxia may occur in nonacclimatized subjects with reduced altitude tolerance at and above 4000 m.

Findings of possible impairment of higher cognitive functions at high altitude are still controversial. Recent studies have more specifically studied what is sometimes called mountaineer's high, which in some ways resembles the syndrome associated with lesions in the frontolimbic loops. The similarity in the patterns of cognitive and emotional deficits after frontal lobe impairment and in the high-altitude syndrome is best accounted for by the fact that the prefrontal and orbitofrontal areas and their connections to the limbic centers are among those most sensitive to acute cerebral hypoxia. When three groups of seven men were exposed to simulated altitudes of 3000 and 4500 m, short-term adaptation mechanisms led to a preservation of selected frontal lobe cognitive and emotional functions. Functional hemispheric superiorities for word recognition and affective processing were likewise unaffected, despite a drop in diastolic blood pressure at 4500 m, indicating a beginning central hypoxia in terms of functional impairment of the vasomotor center.

Residual effects As in diving medicine, those in high-altitude medicine express great interest in the possibility of residual impairment of CNS function following a return to normal pressure. Studies were done of 21 members of an American expedition to Mt. Everest in 1981 prior to the expedition, immediately afterward, and 1 year later using a comprehensive battery of neuropsychological tests. Changes were found for verbal learning and memory, aphasic errors, and fine-motor tempo. Other authors reported similar or consistent findings. Results from a second American expedition in 1985 confirmed the changes found in the 1981 expedition. Furthermore, a simulated altitude exposure similar to the Mt. Everest conditions produced the same impairments in motor speed and persistence, memory, and verbal expression afterward. There was also a significant negative correlation between hypoxic ventilatory response and neuropsychological function measured after the expedition. In other words, subjects with the largest hypoxic ventilatory response showed the greatest neuropsychological decrement. Townes explained this finding by the following hypothesis. Subjects with the highest hypoxic ventilatory response would reduce their arterial pressure of CO_2 the most and

therefore develop the most cerebral vasoconstriction. As a result, this would cause the most severe cerebral hypoxia, even though their arterial pressure of O_2 would actually be higher than in subjects with the smaller ventilatory response to hypoxia. Ward and colleagues found that this correlation between hypoxic ventilatory response and residual impairment of CNS function led to a paradox: the climber who is endowed by nature to go the highest is likely to suffer the most severe CNS damage.

Concluding Remarks

Both diving and high-altitude climbing are potentially dangerous. It requires time and patience to master all the skills necessary to move safely at deep depths and in mountain country. Vigilance and emotional stability are important, and extreme sensation seekers are not as likely to function effectively as more self-sufficient people. Those who are obliged to live harmoniously in close proximity for long periods of time in a high- or low-pressure environment should be stable, loyal, and have both a social and an intellectual tolerance for their companions.

Modifiers of the Rank–Physiology Relationship
Hierarchies, Humans, and Stress-Related Disease

Glossary

<i>Primate personality</i>	Stable patterns of behavioral style, emotional responsiveness and social roles.
<i>Dominance hierarchies</i>	The collectivity of an array of reasonably stable asymmetries in dyads of animals is competing for limited resources.
<i>Psychosocial stressors</i>	Stressors, in a social context, in which there is either anticipation of a challenge to homeostasis (without it having yet occurred) or in which there is no threat of a challenge whatsoever.

Whether one is a professional zoologist or a casual observer of animals in a zoo or on a public television special, few can resist the pull of non-humans primates. Part of the fascination with them is due to their intelligence, and part to their unnervingly close relationship to us. Perhaps the strongest pull, especially when considering the apes and the Old World monkeys, is the force of their individuality – these are

long-lived organisms with strong, pungent personalities and temperaments. For the psychobiologist, an irresistible question is whether there are physiological correlates of these individual behavioral differences and, if such physiological differences exist, whether they are causes or consequences of the behavior.

Stress physiologists have examined this question for a long time, framing it in the context of the stress response and stress-related disease. Do individual differences in primate behaviors, in social rank within the dominance hierarchy, or in personality predict differences in the quality of the stress response? Do they predict differences in patterns of stress-related disease? The answers to these questions are complex, and the very complexity is what offers the greatest insight into the human condition. To best appreciate the complexity, a brief overview of primate social systems will be helpful.

Background: Primate Sociality

As befits our close phylogenetic relatives, the primate order is arguably the most flexible, varied, and catholic of any in the animal kingdom. Primates can be found in ecosystems ranging from the most severe of deserts in Africa to snowy regions of north India and Japan, from thick rainforests to open savanna, from flat plains to steep mountainous regions. They are equally varied in their diet, ranging from strict vegetarians to organized hunters. Given this heterogeneity, it is not surprising that there is an enormous range of primate social systems, ranging from solitary, to small related groups built around male–female pair bonds, to fusion/fission societies involving hundreds of individuals with complex patterns of

polygamy and polyandry. Nonetheless, there are some themes common to most primate species.

First, with the exception of the few rare solitary primate species (such as the orangutan), these are profoundly social animals; the behavior of most primates outside the context of their group makes little sense. As but one measure of the importance of sociality, across the more than 150 primate species, the size of the cortex (relative to total brain weight) positively correlates with the size of social groups in that species. Second, most primate societies have exogamy of one sex, that is, the adolescents of one sex leave the group at puberty, transferring to another group as an inbreeding-avoidance mechanism. Among chimpanzees, for example, it is females who transfer, whereas it is males among the baboons and macaques. As a result, the gender that does not transfer spends its entire life in its natal group, surrounded by same-sex relatives and its mother. Thus, within any such primate society, it is impossible to understand the behavior of one of the sexes without considering the complexities of interactions among kin – cooperative coalitions among chimpanzee brothers or baboon sisters, aunting behavior by female macaques that increases the likelihood of a sister's child surviving, and so on. Finally, even in the most bountiful of ecosystems, resources are not infinite and, in most primate societies, are typically divided up unevenly along lines of conventionalized asymmetry referred to as dominance hierarchies. In a stable dominance hierarchy, limited resources are not contested with bloody tooth and claw. Instead, animals are smart enough to understand the status quo of the dominance hierarchy, allowing it to substitute for overt competition. Accordingly, the social rank of an animal affects its quality of life to an enormous extent.

The phenomenon of dominance hierarchies has long fascinated primatologists, as it can be the most immediate and dramatic version of individual differences in the behavior of these animals. Thus, when stress physiologists became interested in the psychology of individual differences among primates, they first focused on social rank.

Social Rank and Stress Physiology

The earliest theorizing in the field was badly derailed by the influence of the executive stress syndrome studies of the 1950s. This work seemed to suggest that monkeys with executive control over resources were more prone toward ulcers than monkeys without control, and was widely interpreted as evidence of the increased stressfulness of dominance. These findings were subsequently shown to be spurious, due to

nonrandom selection of subjects. Specifically, in order to facilitate the learning of the operancy performed as the executive task, animals were prescreened, and the most emotionally reactive ones were made executive animals.

Finally, freed from these erroneous findings, primatologists interested in the rank–health relationship turned their attention to rodent studies, which were pioneered by James Henry. These produced a fairly consistent picture. Subordinate animals (as typically detected by the outcome of paired fights) showed indices of chronic stress, including elevated circulating glucocorticoid levels, hyperplastic adrenals, immune suppression, reproductive problems, and hypertension. As studies began with non-human primates, it was expected that the same would be seen. This was reinforced by insights into the psychological variables that modulate the stress response. Specifically, classic studies by John Mason, Jay Weiss, Seymour Levine, Martin Seligman, and colleagues showed that the same physical stressor would trigger a larger or more prolonged stress response if the organism lacked a sense of control, lacked a sense of outlets, lacked predictive information about the stressor, or interpreted events as worsening.

Studies of an array of primate species demonstrated that lower-ranking individuals in stable dominance hierarchies disproportionately suffer those psychological stressors. They lack control and predictability, for example, potentially spending minutes obtaining a food item that can be seized from them, finding a grooming partner only to have the bout disrupted by someone else, being subject to unpredictable displacement aggression if someone else was having a bad day. Moreover, they typically lack the means to release frustration by displacing aggression onto someone else.

This generated the expectation that subordinate primates would have a maladaptive profile that would include stress responses that were hyperactive basally or sluggish in recovering from a stressor, and greater vulnerability to stress-related disease. This was precisely what was reported, during the 1980s and 1990s. Work by, among others, Jay Kaplan, Carole Shively, Deborah Gust and colleagues with macaques, Robert Sapolsky with baboons (a wild population, in this case), Barry Keverne and colleagues with talapins, Kirk Manogue and colleagues with squirrel monkeys, and Eberhart Fuchs and colleagues with tree shrews demonstrated that subordinate individuals displayed elevated basal glucocorticoid levels and negative feedback insensitivity, elevated resting blood pressure, a sluggish cardiovascular response to a stressor and a sluggish recovery, suppressed levels of good (i.e., HDL) cholesterol, impaired fertility and a

reproductive axis more readily suppressed by stress, fewer circulating white blood cells, an enhanced risk of atherosclerosis, increased endogenous benzodiazepine signaling, and less genesis of new neurons in the brain. Furthermore, when group membership was being manipulated among captive animals, and physiological measures were taken before and after formation of the group (and thus of the dominance hierarchy), it was clear that the physiological differences arose as a consequence of the rank differences. Finally, an array of subtle studies showed that these stress-related indices were far more a function of the psychosocial aspects of subordination, rather than one of the overt physical insults of rank.

These findings were readily interpreted as indices of the stressfulness of social subordination. A number of individuals carried out detailed studies uncovering the reductive mechanisms explaining these patterns. For example, Kaplan and colleagues have done detailed studies demonstrating that the stress-induced suppression of estrogen levels in subordinate female macaques helps contribute to the increased risk of atherosclerosis. Sapolsky and colleagues have shown that basal hypercortisolism of the subordinate baboons arises for many of the same reasons that hypercortisolism does in human depression (i.e., hypersecretion of corticotropin-releasing hormone [CRH] at the hypothalamic level, a partial compensation at the level of the pituitary via blunted sensitivity to CRH, and feedback resistance in the form of insensitivity to dexamethasone).

Despite this seeming clarity, major contradictions to this picture were emerging. David Abbott, working with marmoset and tamarin monkeys, and Cavigelli, working with feral lemurs (as well as Scott Creel, studying an array of non-primate species, including African wild dogs and dwarf mongooses), were reporting diametrically opposite findings, namely, that it is dominant individuals that show the indices of overactivated stress responses.

By the mid-1990s, a widespread impression was emerging that there was, in fact, little consistent relationship between primate social status and stress-related disease. The most recent work in the field has shown that this is not the case. Instead, the rank–health relationship can be modified dramatically by an array of additional factors.

Modifiers of the Rank–Physiology Relationship

What Is the Meaning of Rank in a Species?

Among the macaques and baboons, subordination is a state forcibly imposed from above by way of

aggression or harassment by dominant individuals; resources are divided with marked inequity along the lines of rank. Such despotic dominance systems generate considerable stress for subordinates. The situation for marmosets and tamarins, in contrast, is quite different. Among these New World monkeys, social groups of six to eight animals consist of a pair-bonded dominant pair and a number of subordinate individuals. Critically, these social groups are typically extended families of relatives, and successful reproduction involves cooperativity among them. A subordinate animal is usually a younger relative waiting her turn and helping older relatives with child-care in the interim, and is rarely subject to displacement aggression. This goes far to explain Abbott's reports of dominant animals showing the preponderance of stress-related physiology. One meta-analysis examined all studies of rank–basal glucocorticoid relationships in non-human primates (seven species, both genders), ranging from cases in which subordinate animals have far lower basal levels than dominant animals (marmosets and tamarins) to those in which subordinates have far higher (talapoin and baboons). Across these species, a significant predictor of such relative glucocorticoid levels was the degree to which subordinates were subject to the harassment and displacement aggression typical of despotic dominance systems.

How Is High Rank Maintained in the Particular Primate System?

In many primate social systems, rank can change over time, raising the question of how a high-ranking individual holds on to that rank as long as possible. In some cases, this involves frequent and overt aggression aimed at subordinate individuals, with the result that dominant animals are involved in the highest rates of fighting. In contrast, in other cases, well-entrenched dominant animals have the lowest rates of aggression, maintaining their dominance through little more than subtle psychological intimidation. A number of studies now demonstrate that in the former case, subordination is not associated with elevated basal glucocorticoid levels, whereas in the latter it is.

How Stable Is the Dominance Hierarchy?

In many primate social systems, rank is inherited at birth, remaining static throughout life. However, even in systems in which rank shifts over time, there can be long periods of hierarchical stability (i.e., where the dominant individual in any given dyad wins the vast majority of dominance interactions, thereby reinforcing the status quo). In such cases,

dominant individuals have the abundant physical and psychological advantages of their lofty rank. Occasionally, hierarchies will become unstable (due to some key individual entering or leaving the troop, a death or injury, or the formation or dissolution of a key coalition), and there will ensue an unstable period of dramatic, frequent shifts in rank until the hierarchy restabilizes. This period will produce high rates of aggression and competitive interactions among individuals, unpredictable formation and disintegration of coalitions, and low rates of socially affiliative behaviors. Under such circumstances, it is high-ranking individuals, at the center of the competition, who have the least control and predictability over events around them. As shown by numerous investigators, during such unstable periods, it is no longer the subordinate individuals who have the highest basal glucocorticoid levels or the greatest risk of developing atherosclerosis.

What Coping Strategies Are Available to Subordinate Animals?

The magnitude of the stress response is a function of the severity and frequency of stressors to which an individual is exposed and, just as importantly, the availability of coping outlets. In primates, some coping outlets are positive (grooming, being groomed, physical contact with another animal) and others are negative (displacing aggression on to another animal). Across the primate species studied, the more such outlets are available (both positive and negative), the lower the basal glucocorticoid levels. There are not sufficient data, however, to determine whether positive or negative outlets are more physiologically protective.

How Readily Can Subordinate Animals Avoid Dominant Ones?

In a rather simple and intuitive way, subordinate animals who can readily evade the attention of dominant individuals are likely to be subject to fewer stressors. This point helps explain some seeming contradictions in the literature. For example, studies of wolves have shown that in captivity (where subordinate individuals are markedly constrained in their ability to avoid dominant animals), it is subordinate animals who have the highest basal glucocorticoid levels. In contrast, in feral wolf populations, this is not the case.

What Is the Social Milieu of a Particular Primate Group?

Primate social systems not only vary between species, but also vary among different populations of the

same species. In some cases, this reflects ecological or genetic issues, but often, it reflects a fluke of demographics of the group and the personalities of its members. As such, the social milieu of a particular group can modify the rank–health relationship. Work by Gust and by Sapolsky has focused on social systems (of female macaques and male baboons, respectively) in which subordination is typically associated with elevated basal glucocorticoid levels. However, this is not observed in troops with atypically low levels of displacement aggression on subordinates and/or high levels of social affiliation.

What Is an Individual Animal's Experience of Life in Its Social Group?

While the generic features of a primate's social group (e.g., rates of reconciliation, extent of hierarchical stability) may be a significant predictor of stress-related physiology, so is the personal experience of those variables. For example, in a pair of studies of macaques, the severity of basal hypercortisolism varied as a function of how often individual animals were subject to dominance or aggressive interactions, or how often they were given affiliative support. Similarly, in a study of wild baboons during a period when the hierarchy was destabilized by a highly aggressive transfer male, the frequency with which that male attacked females was highly predictive of the extent to which they were immunosuppressed. Strikingly, in that study, females who had not been subject to such displacement aggression showed no evidence of immune suppression. Thus, these stress-related physiological markers do not respond to the abstract features of life in a particular troop (i.e., this is a troop with high rates of reconciliation/displaced aggression/coalitional fighting ...), but to the individual's very concrete personal experience of events in the troop.

What Is the Personality of the Animal in Question?

One of the most striking factors influencing individual differences in stress-related physiology among primates is personality. The notion of personalities among non-human primates was long ignored in many circles of primatology, being viewed as unacceptably anecdotal and anthropomorphic. Recent and rigorous work has shown there to be consistent and stable differences among individuals in their temperament, patterns of impulsivity, tendencies toward sociality, the social roles they will assume within the group, and so on. With those findings has come an interest in whether those differences predict different profiles of stress-related physiology.

As one example, Stephen Suomi and colleagues, Ned Kalin, as well as Kaplan, Steven Manuck, and colleagues reported stable personality differences in macaque monkeys in their extent of reactivity to novelty. Such traits are apparent very early in life, and the high reactor animals whose behaviors are more disrupted by novelty are hypercortisolemic throughout life and more prone toward atherosclerosis.

In another series of studies, Sapolsky and colleagues examined personality differences among wild baboons, after controlling for rank. Two clusters of traits predicted elevated basal cortisol levels. The first related to patterns of male–male competition; hypercortisolism was observed among individuals who were least capable of differentiating between threatening and neutral interactions with rivals (i.e., they responded to both as if they were provocative), were least likely to control the initiation of a fight, and were least capable of differentiating between winning and losing fights (i.e., both outcomes equally disrupted their social behavior thereafter). A second, independent cluster demonstrated hypercortisolism among the males with the lowest rates of social grooming or contact with females, or play with infants. These findings were interpreted as showing greater endocrine indices of stress among animals with the least amounts of control and predictability about stressors and the fewest sources of social coping outlets.

Hierarchies, Humans, and Stress-Related Disease

A number of investigators have examined human hierarchies in the hopes of correlating rank differences with differences in stress physiology. Outcomes of athletic competitions, military ranks, and position within a corporate workplace have all been considered as examples of human hierarchies, and differences in physiology have been reported. Other investigators have criticized these studies due to artificiality of these rankings (e.g., how much can rankings in a college wrestling tournament tell us about cardiovascular disease susceptibility?), the confounding ability of humans to be in more than one hierarchy (i.e., the low-ranking individual working in the mailroom of a corporation might, at the same time, be captain of the company softball team and consider that to be the more relevant hierarchy), and the human capacity for rationalizing and externalizing what would be perceived as being a low rank.

Some investigators have suggested that low socioeconomic status (SES) can be viewed as the most valid and pervasive example of low rank in a human, carrying with it many of the psychological stressors seen

among many low-ranking non-human primates (lack of control, predictability, or outlets). Low SES carries with it an enormously increased risk of a broad range of diseases, and careful study by pioneers such as Michael Marmot, Richard Wilkinson, Nancy Adler, and Ichiro Kawachi has shown that this SES gradient can not be explained by differences in health-care access and can only be minimally explained by differences in education or in exposure to risk factors and protective factors. In light of those findings, some researchers have suggested that part of the SES gradient of disease can be viewed as reflecting the psychosocial stressors of poverty. In support of this is not only the fact that some of the alternative explanations can be ruled out to some extent (e.g., a striking bit of evidence against the idea that the SES gradient is due solely to differential health-care access is the robust presence of such gradients in countries with universal health care), but also the fact that diseases that are probably the most stress sensitive (psychiatric disorders and cardiovascular disease) show the steepest gradients.

Glossary

<i>Acquired immunity</i>	The components of the immune system that require time (several days) to respond to antigens and are highly specific for an antigen.
<i>Antibody</i>	A protein secreted by B cells that binds to antigens and leads to their destruction and removal, also called immunoglobulin.
<i>Antigen</i>	Any substance that is recognized by the immune system as not belonging to the body (not self); includes viruses, bacteria, tumors, and tissue grafts.
<i>Cytokines</i>	Protein messengers made by a variety of cells including lymphocytes and phagocytes that regulate the immune response and affect central nervous system activity.
<i>Innate immunity</i>	The components of the immune system that respond immediately in the presence of antigens as a rapid nonspecific response, a first line of defense; includes neutrophils, natural killer T cells, and macrophages.
<i>Lymphocytes</i>	The cells of the immune system, including B cells (make antibodies), T cells, (regulate the immune response and destroy foreign cells), and natural killer

(NK) cells (first line of defense against tumors and virally infected cells; also regulate the immune response).

Phagocytes

The cells of the immune system that process antigens in preparation for activating the immune response; include neutrophils and macrophages.

Psychoneuro-immunology

An interdisciplinary science that examines bidirectional interrelationships among immune, neuroendocrine, and behavioral processes

Simian immunodeficiency virus (SIV)

A virus found only in monkeys that is the best model for human immunodeficiency virus (HIV) available to scientists.

In this article, the utility of animal models is described with a focus on nonhuman primates, followed by a simple overview of the immune system. The area of immunology is growing by leaps and bounds, and as such it is elusive with regard to any review that serves the entire discipline with any justice. The growing area of psychoneuroimmunology (PNI) suggests that there are important regulatory relationships between the brain and the immune system and furthermore that these relationships are bidirectional. The study of these relationships in nonhuman primates is of particular importance for improved understanding brain immune relations in humans due to the great physiological and behavioral similarity of the two groups. The following discussion focuses on several areas of investigation that have implications for immune and behavior relationships in nonhuman primates: prenatal and postnatal experiences, social relationships, and aging.

Animal Models

Animal models are used in a variety of biomedical studies because they permit the control of a number of factors not possible with human subjects. An adequate animal model of any human condition must fulfill several criteria, including a common phenomenology, etiology, underlying pathophysiology, and effective treatment. The evolutionary proximity of humans and nonhuman primates (e.g., monkeys and apes) makes the nonhuman primate a frequently studied model for both human health and disease. The most obvious similarity to humans resides in the

social nature and behavioral characteristics of non-human primates. In addition, nonhuman primates offer a unique opportunity for studying brain-immune relationships. It is likely that the phenotypic traits shared by humans and nonhuman primates are homologous, that is, that they are related to a common ancestral origin. Thus, they may share similar design features. These similarities are important for disentangling complex biomedical problems.

The Immune System

The immune system is a highly regulated system with numerous redundancies and backups. Simply put, the responsibilities of the immune system can be characterized by the three Rs: recognition, removal, and regulation. The immune system must recognize or differentiate self from not self (antigens or foreign substances) and respond appropriately. The antigen might be a simple microorganism located in a cut to a tumor developing in the lungs. Once an antigen is recognized as not self, it must be removed or destroyed by host defense mechanisms. This very complicated process is regulated by immune cells that communicate via complex proteins called cytokines, endocrine hormones, and neurotransmitters derived from neural structure. There are innate processes that respond immediately to the antigen until the acquired system can respond to the foreign intruder. The ability of natural killer (NK) cells to immediately destroy tumors or virally infected cells illustrates the actions of the innate immune system. The presence of specific antibodies protecting the individual against flu, following the administration of a flu vaccine in the fall, exemplify the actions of the acquired immune response. Acquired immunity is a slower and highly specific process; flu protection after vaccination does not occur until approximately 14 or more days after a person receives the vaccine. This response is also a highly integrated response of the immune system.

These systems are not independent but act together closely to control infection and disease. The innate system forms a first line of defense until the acquired system can develop responses specific for the pathogen. It might take from several days to weeks before the acquired response is at full capacity. The innate and the acquired response are regulated by the actions of cells of the immune system, including lymphocytes (T cells, B cells, and NK cells) and phagocytes (neutrophils, macrophages, and eosinophils). T cells, NK cells, and macrophages secrete a number of protein messengers (cytokines) that are critical in the regulation of the response. The capabilities of the immune system can be measured in either tissue culture

systems (*in vitro*) or in the intact organism (*in vivo*). *In vivo* measurements are preferred over *in vitro* assessment because the system is studied under naturally occurring conditions. For example, specific antibodies seen after immunization with a foreign protein represent the final output of a highly integrated response of the immune system. The antibodies in the blood reflect the initial recognition and processing of the antigen by phagocytic cells; release of regulatory cytokines by T cells, NK cells, and macrophages; and interactions with neural and hormonal factors resulting in the final production of antibody by the B cells. One of the first reports on stress in nonhuman primates described the suppressive effects of unpredictable and generally poor housing conditions of monkeys on their antibody levels after immunization.

Prenatal Experiences Modify Postnatal Immune Competence of the Offspring

The prenatal environment contributes significantly to postnatal neurobehavioral developmental and immune competence and as such is a significant contributor to individual differences in the overall regulation of the hypothalamic-pituitary-adrenal (HPA) axis and immune system. The mother and the developing fetus form a highly regulated amalgamation that has received considerable attention with regard to the fetal origins of later medical conditions in the offspring. Stress in the mother is synonymous with stress in the developing fetus. More specifically, prenatal stressors (behavioral and/or pharmacological, e.g., dexamethasone or adrenocorticotrophic hormone, ACTH) of pregnant rhesus monkeys are associated with a cascade of postnatal effects in the fetus. The power of prenatal stressors is indicated by the fact that they are sufficiently pervasive to redirect the gender-specific development of the offspring. Although the offspring are healthy and normal at birth, the effects of prenatal stress are reflected in a dysregulation of immune responses and a more responsive HPA axis in infants born to these prenatally challenged mothers. Immune effects include suppressed cytotoxic-like activity of lymphocytes, depressed proliferative responses, and reduced cytokine production by lymphocytes. The timing of the stressor during gestation (e.g., early vs. late) affects the direction of the specific impact on immunoregulation for some of these measures. That is, early gestational stressors are associated with enhanced mixed lymphocyte responses (MLR) responses toward syngeneic cells from the mother or father, whereas late gestational stressors are associated with reduced MLR to the same targets. Thus, the nature of prenatal stressors is complicated but nonetheless powerful. Prenatal stressors impact placental transfer from

mother to fetus, affecting the transfer of maternal immunoglobulins and iron. These effects lead to reduced levels of beneficial bacteria in the gut of the offspring.

Postnatal Experiences Have Acute and Long-Term Consequences

Early experience effects are not limited to events during the prenatal period but extend to the postnatal period as well. Behavioral challenges are similar in their impacts on later immune and HPA regulation. For example, significant life challenges such as brief maternal separations that might occur during the breeding season when mothers leave their offspring to mate with males in the troop, matrilineal dominance status, or the quality of maternal care have significant effects on the immune regulation in nonhuman primates, both in the field and in laboratory settings. Wild-born offspring of low-ranking matriline, for example, show greater immune and HPA perturbations to acute challenges as adolescents. In the laboratory, social-separation experiences such as the removal of the mother from the infant for brief periods of time produce a number of disturbances in both *in vitro* and *in vivo* immune parameters. Acutely, *in vitro* immune measures such as NK activity and activity of macrophages are elevated, whereas other markers are suppressed. Indeed, specific antibody levels following immunization at the time of separation are reduced and the magnitude of this reduction is greatest in the most distressed monkeys. These early separation experiences have also been shown to impact immune regulation over an extended time period, such as reduced *in vitro* markers of the T-cell function and an elevation in markers of the innate system, namely NK activity and the activity of the macrophage system.

Postnatal pharmacological challenges such as antidepressant drugs administered to young monkeys can have long-lasting effects on immune competence, resulting in lower specific antibody responses to antigenic challenge and increased reactivity of the HPA axis. Altered HPA regulation is one of many contributing factors to dysregulated immune function. The overarching observation is that, if something stressful happens to the mother-infant unit prenatally or the infant postnally, it is very likely to result in a disruption of the immune system, sometimes in subtle but important ways. These observations also indicate the utility of nonhuman primate models, with their shortened life cycle and the researchers' ability to control environmental exposure to pathogens that will surely impact the developmental trajectory. This makes the nonhuman primate model ideal for studies of aging.

A critical question facing the field of psychoneuro-immunology is the interpretation of the functional significance of these *in vitro* measures. As addressed earlier, *in vivo* measures are most likely to reveal important consequences mediated by immune activity that might not be indicated by *in vitro* measures. The implications of early challenges and stressor experiences are best exemplified by studies of monkeys infected with SIV, a nonhuman primate model for acquired immunodeficiency syndrome (AIDS). There is considerable variability in the disease course of AIDS after infection with human immunodeficiency virus (HIV). A significant question for understanding the pathophysiology of this virus is: Why do some individuals infected with HIV progress rapidly and become quite ill and others infected with the virus remain asymptomatic? In retrospective studies of rhesus monkeys infected with SIV, researchers found that the early developmental history of the monkeys contributed significantly to disease course. Thus, monkeys that experienced repeated housing changes early in development or were reared with peers rather than their mother showed a more rapid progression in indicators of virus activity. Furthermore, social reorganization stress at the time of viral inoculation was also associated with reduced survival. Moreover, recent studies from our group also observed that monkeys who progressed most rapidly following inoculation with SIV had reduced activity of cytotoxic T-cell (CD16+ lymphocytes) function before exposure to the virus and independent of early experiences. Although, many potential influences of early experiences on both immunoregulation and disease resistance in adult monkeys have been demonstrated, recent studies also indicate that the risk for rapid progression may rest in genetically determined aspects of immunoregulation as well.

Social Relationships Affect Immunoregulation

We have learned the most regarding the relation between behavior and immunity from observations of the negative consequences of stressors. Social psychology has shown for many years that the presence of social support in humans has positive consequences for health and well-being. There is growing evidence in nonhuman primates that a number of aspects of social relationships can also have positive consequences for markers of health and immunity. Most nonhuman primates are social creatures with their lives organized around social interactions with other members of their group. During times of social challenge, the presence of another monkey is important for reducing the negative endocrine and immune

consequences of the stressor. The negative consequences of maternal absence on behavior and physiology are significantly reduced in the presence of other monkeys who interact with the separated monkey. These social interactions may include affiliative behaviors, such as sitting nearby, play, and/or grooming. Being groomed by another monkey is quite effective in reducing heart rate to levels comparable to those noted during sleep. Grooming in monkeys strengthens social ties and facilitates reconciliation following fights between monkeys. Heart rate recovers rapidly following an aggressive interaction if one of the monkeys is groomed by the other involved in the fight. The immediate immune consequences of these behaviors have not been determined.

The relationship between dominance status in nonhuman primates and immune regulation is not as clear as we might expect. A high social rank does not necessarily imply enhanced immune capacity. Immune status assessed by *in vitro* methods in monkeys with high social status does not differ from low-ranking monkeys under stable social conditions nor do acute short-term stressors modulate these measures in a manner predicted by social status in the group. However, if the specific antibody responses to an antigen, an *in vivo* measure, are assessed under stable conditions, low-ranking monkeys mount a larger response than high-ranking monkeys. High rank may carry with it some subtle negative consequences. It appears that specific affiliative behaviors are most critical in modulating the impact of stressful social conditions in nonhuman primates, not unlike the role of social support for humans. Furthermore, the assumption that stress suppresses immune regulation is no longer entirely correct because acute stressors and challenges can enhance aspects of the inflammatory response.

Individual Differences in Immune Regulation

Monkeys differ along a number of behavioral and physiological dimensions. The concept of individual differences has received more attention from researchers in PNI. In the face of considerable variability in outcome following seemingly similar challenges, we may observe a wide range in the levels of immune measures even under resting conditions. Epidemiological research has tended to focus on demographic characteristics such as gender, age, socioeconomic status (SES), race, and so on in partitioning outcome variability. The long-term consequences of these factors have received considerable attention in a concept called allostatic load, the cumulative effects of long-term stressors that ultimately push the adaptational

capacity of the stress response system beyond its capacity. However, there are individual factors that contribute to the extent to which these stressors affect immunoregulation.

Recent observations in monkeys have suggested that behavioral characteristics or traits unique to each monkey are influential in determining these outcomes. For example, sociability, or the tendency to engage in affiliative interactions with other monkeys, is associated with more rapid clearance of the virus in SIV-inoculated monkeys. These findings support the observations that social affiliation reduces the negative consequences of social challenge. Under free-ranging conditions, monkeys characterized as irritable (e.g., active, irritable, and aggressive) tended to have higher active infection with cytomegalovirus (CMV), a virus common in these animals. Thus, in addition to demographic characteristics, individual differences in behavioral traits also contribute to immunological variance. Other aspects of traitlike behaviors on nonhuman primates (e.g., personality) affect immune regulation to the extent that animals' relative sociality in social groups affect their specific antibody response following relocation. Monkeys rated as low in sociability (e.g., motivation to seek social interactions with others) had reduced specific antibody responses during this challenge.

Environmental Factors Influencing Immunoregulation

The complex nature of nonhuman primates presents the researcher with a number of challenges to provide for their psychological well-being. These manipulations are strictly monitored by federal (U.S. Department of Agriculture, USDA) and private (Association for Assessment of Laboratory Animal Care, AALAC) agencies. The simplest way of achieving this goal is through social housing and avoiding single-individual housing of nonhuman primates. Only a limited number of studies have actually investigated the impact of environmental enrichment on immune responses *per se*. A large number of studies, however, have investigated the impact of environmental enrichment on social behaviors of macaque monkeys. The provision of foraging enrichments (e.g., foraging boards and small preferred food treats mixed into the bedding) and manipulative devices such as simple toys significantly reduces the number of stereotypical behaviors and increase positive social interactions in nonhuman primates. As mentioned earlier, unpredictable housing experiences are associated with immune dysregulation as reflected in an attenuated specific antibody responses. Observations in SIV-infected macaques also indicate that the number of cage changes

occurring in advance of inoculation also impact the response to viral inoculation; that is, numerous cage moves, which represent a significant social stressor, are associated with more rapid progression and fatality to the virus. Features of housing for research animals that were neglected in the past have also been shown to impact experimental outcomes in significant ways.

Mechanisms of Brain-Immune Interactions

If behavior (i.e., the central nervous system) is likely to affect the regulation of the immune response, there must be potential pathways for these interactions. Indeed, there are two major means of brain and immune communication: direct neural innervation of immune organs by the autonomic nervous system and soluble blood-borne factors (i.e., cytokines and endocrine hormones). Nerve fibers of the autonomic nervous system come in close proximity to immune cells in lymphoid organs such as the spleen, thymus, and lymph nodes. Stress hormones such as cortisol are present in the blood during times of environmental and social challenge. Both of these routes, activated during stress, provide the means for neural-immune interactions. In addition, the cells of the immune system possess receptors for the neural and hormonal systems that permit the various neurotransmitters and hormones to affect immune regulation.

This is not a one-way street; the actions and products of the immune system itself also influence the central nervous system. A major component of illness is the associated changes that include sickness behaviors such as fatigue, sleep changes, changes in cognition, and loss of appetite. In many respects, these behaviors associated with cytokine release parallel major depressive disorders, and it has been argued that sickness behavior is one of many factors that underlie depression in clinical populations. Only a few studies have approached sickness behavior in primate models, but cytokines such as interleukin (IL)-1 and interferon- α have been observed to produce sleeplike behavior, advance rapid eye movement (REM) onset, and activate the HPA axis. These effects are consistent with observations in rodent models of sickness behavior and suggest that similar relationships to behavior exist in nonhuman primates as well.

Immune Senescence in Nonhuman Primates

It is generally assumed that aging is associated with immune downregulation. However, observations in successfully aging seniors have indicated that this

may not universally be the case. As a group, older monkeys demonstrate reduced *in vitro* immune responses, such as lymphocyte proliferation and natural cytotoxicity. Functional measures indicate that, compared to a younger monkey, the older monkey's response to challenge with a trivalent flu vaccine is impaired. The extent to which cytotoxic responses are maintained with aging is an important predictor of long-term survival. It has been pointed out that the selection of old animals from a colony creates an inherent bias because they are really only members of a survivor cohort. In general, evidence supports the natural cytotoxic response as a potential proxy marker for successful aging and viral suppression in both old and younger animals.

Interestingly, feeding and exercise habits contribute significantly to the relationship between aging and immune senescence. For almost a century, it has been recognized that caloric restriction (not to be confused with malnutrition) is associated with a number of health benefits, including reduced morbidity and mortality in rodent models. A study that began in the late 1980s fed two groups of rhesus monkeys nutritionally fortified but either calorically restricted or *ad libitum* diets. As these monkeys now approach their senior years, a number of studies are underway to evaluate the impact of this restricted diet on brain structure, neuroendocrine regulation, and immune competence. Immune assessments have indicated attenuated age-related changes among the calorically restricted monkeys in many parameters, including *in vitro* cellular proliferation, cytokine levels, *in vitro* cytokine production, and cytokine gene expression, most notably in interferon- γ . These initial results suggest that some of the untoward aspects of aging are potentially attenuated in association with dietary restriction.

Summary

Nonhuman primates provide excellent models for research in PNI. The complexities of their behavioral interactions serve as an outstanding model for behavior and immune interactions relevant to humans. Early experiences affect immune regulation beyond the developmental period. Negative events experienced early in development contribute to increased risk for disease; however, social factors can reduce the impact of many of these negative experiences. Individual differences in behavioral characteristics also contribute to differences in immune regulation. There are abundant means whereby the immune system and the brain are able to interact. Understanding of these interactions poses a significant challenge for PNI in the twenty-first century.

Nonhuman Primates as Animal Models

Behavioral Influences on Risk Factors for Cardiovascular
Disease

Behavioral Influences on Atherosclerosis

Behaviorally Induced Abnormalities in Vascular Reactivity

Summary

Glossary

Abnormal coronary vascular reactivity The tendency for coronary arteries to lose their ability to dilate rather than constrict as demand for blood is increased.

Atherosclerosis A gruel-like accumulation of fatty substance in the intima (inner layer) of the large muscular and elastic arteries of the body.

Beta-blocker A class of drugs that inhibits the activation of the sympathetic nervous system (i.e., heart rate, blood pressure, and

cardiac output) by blocking the response of β -adrenergic receptors in the arteries and heart.

Coronary heart disease (CHD) A disease spectrum subsuming myocardial infarction (heart attack), angina pectoris (ischemic chest pain), and disruptions to the rhythm and electrical activity of the heart.

Dominant/subordinate social status The position that an animal occupies in a pecking order. High-status animals (dominants) predictably defeat low-status animals (subordinates) in competitive encounters. Subordinate animals generally exhibit signs of stress (e.g., exaggerated release of cortisol from the adrenal cortex and behavioral withdrawal).

Endothelium The inner wall of the artery; a normally functioning endothelium causes the artery to dilate and constrict appropriately in response to blood flow.

Heart rate reactivity The degree to which an individual's heart rate increases in response to stressful situations. High heart rate reactivity is probably due to excessive activation of the sympathetic nervous system, and it is associated with the increased development of atherosclerosis in people and monkeys.

Hypertension A sustained increase in blood pressure.

<i>Ischemia</i>	A reduction in blood flow to an organ or tissue, due to obstruction (e.g., a blood clot), arterial constriction, atherosclerosis, or a combination of factors.
<i>Plasma lipids</i>	Fats or fatlike substances (insoluble in water) that include total plasma cholesterol (TPC), high-density lipoprotein cholesterol (HDL), and low-density lipoprotein cholesterol (LDL). In general, $TPC = HDL + LDL$. Elevations in plasma levels of LDL (and the resulting increases in TPC) are highly atherogenic. High plasma concentrations of HDL (the good cholesterol) are protective.
<i>Quantitative coronary angiography</i>	An imaging procedure in which an opaque dye is infused into the coronary arteries, allowing them to be visualized radiographically and measured.
<i>Sympathetic nervous system (SNS)</i>	That part of the involuntary or self-regulating nervous system that controls responses (e.g., heart rate and blood pressure increases) to stressful situations.

Cardiovascular disease is manifested most prominently in human beings as coronary heart disease (CHD) and stroke. Atherosclerosis in the coronary arteries is a usual cause of CHD, whereas atherosclerosis in the cerebral arteries contributes to both transient ischemic attacks and ischemic stroke. Epidemiological and clinical studies have provided considerable evidence that behavioral factors influence the development of cardiovascular disease and the underlying atherosclerosis. However, logistical and ethical considerations prevent many questions regarding risk factors and mechanisms from being addressed directly in people. Animal models offer an alternative means of answering such questions.

Nonhuman Primates as Animal Models

The ideal animal for evaluating behavioral influences on cardiovascular disease would respond to a fat- and cholesterol-containing diet by exhibiting both an intimal accumulation of atherosclerosis in the large proximal coronary arteries and a susceptibility to infarction and ischemia. Furthermore, this animal would resemble human beings in cardiovascular and reproductive physiology and in neurobiology. Finally, the animal's behavioral responses and characteristics would vary along dimensions (e.g., aggressiveness and competitiveness, social support) analogous to those thought important in the epidemiology of atherosclerosis and CHD in human beings. Of all animal models, the nonhuman primates best approximate the foregoing characteristics.

Numerous investigators have used primates to explore one facet or another of the hypothesis that behaviorally evoked, excessive perturbations of the body's principal axes of neuroendocrine response (i.e., the adrenal cortex or the SNS) may produce pathophysiological consequences. Some of these studies provide data regarding the influence of stress on the risk factors for cardiovascular disease (e.g., elevations in plasma lipids and blood pressure) or on mediating factors (circulating concentrations of immune or inflammatory markers), whereas others have focused primarily on the characteristics of atherosclerotic lesions or abnormalities in vascular reactivity to changes in blood flow. Taken together, existing studies present a clear and convincing case that behavioral factors (either stressful environments or particular characteristics of temperament) influence both atherosclerosis and clinical events in ways that have relevance for human beings.

Behavioral Influences on Risk Factors for Cardiovascular Disease

Plasma Lipids

Elevations in plasma lipids (e.g., total plasma cholesterol, TPC; low-density lipoprotein cholesterol, LDL) are associated with the exacerbation of atherosclerosis and increased risk of CHD and ischemic stroke. Thus, behavioral factors may contribute to cardiovascular disease through a mechanism involving adverse changes in plasma lipids. Among primates, the lipids of squirrel monkeys (*Saimiri sciurius*, a New World primate) seem particularly susceptible to behavioral influences. In one study, for example, there was an increase in plasma lipids as animals were transported from South America to a laboratory in the United States. Interestingly, both TPC and LDL declined in these animals after they were put in a secluded environment, but increased again following exposure to a busy laboratory. All of these changes occurred in the absence of any cholesterol in the diet and are attributed most reasonably to the influence of psychic stress. Cholesterol-fed squirrel monkeys are similarly responsive to experimental manipulations; exposure to either a shock-avoidance paradigm (in which the animal presses a lever to avoid a shock) or a restraint box leads to a significant and sustained increase in TPC and LDL.

Among the Old World monkeys, adverse serum lipid profiles have been observed in relation to individual differences in social status and individual differences in heart rate reactivity to stress. In both baboons (*Papio hamadrayas*) and cynomolgus macaques

(*Macaca fascicularis*), for example, subordinate social status is associated with suppressed plasma concentrations of high-density lipoprotein cholesterol (HDL), which is a risk factor for atherosclerosis. Notably, cynomolgus macaques that reliably exhibit exaggerated heart rate responses to psychological stress (e.g., exposure to a threatening object) also tend to have suppressed plasma concentrations of HDL.

Data from Old and New World monkeys suggest that stressful environments, low social status, and exaggerated SNS responsivity to challenge are all associated with potentially harmful plasma lipid profiles. Among human beings, there are also numerous observations relating either elevations in LDL or reductions in HDL to stressful circumstances or particular personality characteristics.

Blood Pressure

Elevated blood pressure (hypertension) is associated with increased risk of CHD and stroke. High blood pressure also exacerbates atherosclerosis in the coronary and cerebral arteries. Numerous studies indicate that behavioral stress can lead to sustained, potentially pathogenic increases in both systolic and diastolic blood pressure. For example, squirrel monkeys trained to avoid a shock by pressing a lever ultimately exhibit increases in blood pressure that persist across experimental sessions. Rhesus monkeys (*M. mulatta*) exposed to a similar manipulation also develop a steady elevation in blood pressure. Further, rhesus monkeys as well as baboons experience sustained increases in blood pressure when light signals and shock are paired and combined with a bar press for the delivery of food (called conflict manipulation). Chronic exposure to loud noise also produces elevated blood pressure in cynomolgus and rhesus macaques. Notably, adult male baboons that typically live together with a number of females in a harem develop hypertension when they are separated from their harems and forced to watch the females feed first. Males also exhibit a hypertensive response when they are separated from their harems and are forced to observe a new male being introduced to these females. These latter manipulations are purely social and more closely model the kind of stress most likely to affect human beings.

Behavioral Influences on Atherosclerosis

Atherosclerosis in Males

Primates typically do not develop atherosclerosis to any significant degree unless they are fed a diet

relatively high in saturated fat and cholesterol, similar to the diet often consumed by people living in industrialized nations. Early investigations used physical restraint or exposure to a shock-avoidance manipulation to provide evidence that psychic stress, in combination with an atherogenic diet, could potentiate atherosclerosis in monkeys. However, social manipulations also influence the development of atherosclerosis in monkeys. For example, when cynomolgus males are housed in groups that either remain stable in composition or that are perturbed (by distributing members across groups), dominant and subordinate animals tend to retain their relative rankings irrespective of social condition (i.e., stable or unstable groups). A quantitative evaluation of the coronary arteries of such animals revealed that monkeys housed in an unstable condition had significantly more coronary artery atherosclerosis than animals in a stable environment but only if they were dominant in their groups. This finding suggests that the behavioral demands of retaining dominant social status in an unstable social setting potentiate atherosclerosis, at least in males of this species consuming an atherogenic diet. A similar pattern was obtained (although with markedly smaller lesions), among animals that consumed a diet modeled on the recommendations of the American Heart Association. Thus, behavioral factors might, even in the absence of dietary provocation, cause damage that could initiate the earliest lesions of atherosclerosis. Subsequent investigations have shown that exposure to the stress of social perturbation for as little as 72 h can cause the degeneration and death of endothelial cells, thus marking the first stage of atherosclerosis progression.

Mediating Role of Sympathetic Nervous System Activation in the Atherosclerosis of Males

Significantly, behavioral effects observed in the social manipulation experiments were independent of variation in serum lipid concentrations and resting blood pressure. Numerous investigators have proposed that recurrent SNS activation in response to behavioral stimulation could promote the development of atherosclerosis and its clinical sequelae. Testing the hypothesis that excessive SNS activation might have potentiated atherogenesis among dominant animals in the foregoing studies, male monkeys in a subsequent investigation were all housed in unstable social groups and fed an atherogenic diet; here, half of the monkeys also received a beta-blocker, propranolol, throughout the 2-year study. Untreated dominant monkeys again had twice the amount of atherosclerosis of their subordinate counterparts,

replicating the results from the unstable treatment condition of earlier experiments. Dominant monkeys treated with propranolol, however, developed less than half the coronary atherosclerosis of untreated dominants and had roughly the same extent of lesion as both treated and untreated subordinate animals. Hence, the more pronounced atherosclerosis characteristic of untreated (i.e., autonomically intact) dominant monkeys, when housed in groups of rotating membership and fed a cholesterol containing diet, can be prevented by the long-term administration of a beta-blocker and is therefore dependent on concomitant SNS activation. Furthermore, the monkey studies also provide evidence that behaviorally induced SNS activation initiates atherogenesis independently of the presence of a high-fat diet. Hence, the endothelial cell death associated with the short-term (72-h) perturbation previously described occurs in the absence of elevated plasma lipids and can be inhibited by pretreatment with a beta-blocker.

Other data from this species further support the speculation that a heightened SNS responsivity to behavioral stimuli increases the risk for atherosclerosis. Specifically, cynomolgus macaques display reliable and significant individual differences in heart rate response (assessed via radiotelemetry) to a standardized social stressor (exposure to an unknown human). Animals can thus be characterized as either high or low in heart rate reactivity to stress. Notably, the atherosclerotic lesions of high heart rate reactors are twice as large as those of their low-reactive counterparts. Taken together, the results of the macaque experiments indicate that some individuals (e.g., high heart rate reactors) may be susceptible to the development of atherosclerosis because of an intrinsic SNS hyperresponsivity to behavioral stimuli, whereas others (dominant individuals in unstable social environments) may be at increased risk because of frequent elicitation of such responses in stressful environments. SNS activation, provoked in either of two ways, may thus provide the common pathway by which pathogenesis is mediated in male monkeys.

Summary for Male Monkeys

The studies of male monkeys relate a behavioral predisposition (social dominance, i.e., successful aggression) and excessive SNS stimulation to the exacerbation of atherosclerosis. Both domains appear to have analogs among human beings. There are other behavioral risk factors, however, about which the studies in male monkeys provide little data or insight. Such factors include depression, sleep disturbances, and a propensity to anxiety or panic, all of which

have been associated reliably with elevated risk of CHD in human beings. Moreover, social support is often believed to be cardioprotective. Although several measures of social support have been evaluated in the foregoing studies of male monkeys, there is no evidence that animals differing by these measures vary in their extent of atherosclerosis.

Sex Differences in Atherosclerosis

The relative sparing of premenopausal women compared to men of similar ages is a prominent feature of CHD, ischemic stroke, and atherosclerosis. Although this phenomenon is sometimes referred to as female protection, it is characterized more accurately as a delay in disease onset, with the incidence curve for women lagging behind that of men by approximately 10 years. The various effects of estrogen are believed to account for most of this sex difference, at least with respect to CHD incidence and underlying atherosclerosis. Not only are premenopausal women protected from CHD, but the provision of estrogen replacement to women immediately prior to or immediately following menopause is associated with a significant reduction in CHD risk (it must be noted that such protection is not apparent when hormone therapy is initiated in women with preexisting disease or who are 10 or more years postmenopausal).

Because atherosclerosis progresses over decades, it is likely that the clinical events occurring in postmenopausal women have their beginnings in the premenopausal years. This conclusion is supported by autopsy assessments showing that by 34 years of age, at least one-third of all women (regardless of race) have raised lesions in their coronary arteries. *In vivo* arterial imaging also demonstrates the presence of relatively extensive focal atherosclerosis in premenopausal women. The observations that atherosclerosis begins premenopausally raises the question of whether there are particular risk factors that place some women on a higher-risk trajectory than others. Considerable effort has been focused on this question in studies employing premenopausal monkeys as a model of reproductive-age women. The major results of these studies are described next.

Social Stress and Female Protection from Atherosclerosis in Monkeys

Investigations using socially housed female cynomolgus monkeys provide evidence that stress-induced ovarian dysfunction eliminates premenopausal protection from atherosclerosis. For example, in one 2-year experiment contrasting the atherosclerosis of socially housed males and females, the females were divided

into groups of five. Each of these groups contained a vasectomized male; additional males were placed together in groups of five. All animals consumed an atherogenic diet. Quantitative evaluation of the coronary arteries at the end of this experiment demonstrated that female protection with regard to atherosclerosis extended only to the dominant animals (i.e., those ranking first or second in their social groups); subordinate females (ranking third or below) were indistinguishable from males. Subordinate females also had five times as many anovulatory cycles and three times as many cycles characterized by luteal-phase progesterone deficiencies as did their dominant counterparts. Notably, females with the most extensive atherosclerosis were all subordinate, and all had marked ovarian endocrine dysfunction. These data suggest that the stress of social subordination may increase the risk of atherosclerosis in females by inducing a relative ovarian endocrine deficiency state similar to that observed in postmenopausal women. Interestingly, investigations in premenopausal women also have linked stress-induced estrogen deficiency to severity of angiographically documented CHD.

In a further study, ovariectomized females were placed in social groups for the same amount of time and fed the same diet as the reproductively intact females just described. The ovariectomized females as a group had significantly more extensive coronary artery atherosclerosis than the intact females. This effect was due entirely to the loss of protection experienced by the ovariectomized dominant animals compared with their intact counterparts. The subordinates, intact and ovariectomized, were affected equally with atherosclerosis. Additional studies have extended these findings by showing that the treatment of premenopausal females with either an oral contraceptive or unopposed estrogen treatment eliminates the difference between dominant and subordinate individuals. Parenthetically, it should be noted that subordinate females tended to be hypercortisolemic compared to dominants, leading some scientists to suggest that the atherosclerosis distinctions between such animals may be mediated in part by the excessive activation of the hypothalamic-pituitary-adrenocortical axis. The fact that dominant and subordinate animals continue to differ in adrenocortical activation – but not atherosclerosis extent – following ovariectomy argues against this hypothesis.

Finally, a recent life-course study demonstrated that premenopausal behavioral and hormonal status predict postmenopausal atherosclerosis outcomes independently of any postmenopausal hormone exposure. Specifically, females that were subordinate in their

social groups – and thus were ovarian-suppressed and estrogen-deficient – developed more atherosclerosis premenopausally and postmenopausally than did their dominant, ovarian-normal counterparts. Significantly, the worsened atherosclerosis of the subordinate, socially stressed individuals could be mitigated by premenopausal treatment with exogenous estrogen in the form of an oral contraceptive. This important set of observations implies for women that premenopausal behavioral and associated hormonal (estrogenic) characteristics establish the trajectory of atherosclerosis progression that ultimately culminates in postmenopausal CHD events. The monkey research thus emphasizes the importance of early pathogenesis and early intervention, a perspective supported by recent reevaluations of clinical trial data.

The different patterns in which social status influences atherosclerosis in male and female monkeys deserves comment. Subordinate female primates, like subordinate and stressed females of many other mammalian species, tend to experience impaired ovarian function. This impairment eliminates female protection from atherosclerosis in monkeys and, by implication, women. Subordinate male monkeys also experience stress, possibly including impaired reproductive activity; however, the physiological sequelae of social subordination among males do not seem to affect the coronary arteries. Instead, dominant males in unstable settings are predisposed to atherosclerosis because they experience marked elevations in artery-damaging SNS activity as they attempt to maintain behavioral preeminence in the face of challenge.

Social Isolation, Depression, and Atherosclerosis in Females

The exacerbation of atherosclerosis in female monkeys is also observed in conjunction with single-cage housing (i.e., social separation). Specifically, females housed in single cages have significantly more coronary artery atherosclerosis than comparably treated animals housed in social groups. Single-caged animals are most similar in atherosclerosis extent to socially housed subordinates. Interestingly, this worsening of atherosclerosis among single-caged females is not related to ovarian impairment; rather, such animals exhibit elevations in heart rate. This latter observation suggests that, at least in female monkeys, social separation exacerbates coronary artery atherosclerosis via exaggerated SNS activity. No similar studies have been done in male monkeys. This outcome in females is, however, consistent with extensive literature documenting the cardioprotective

effects of social support and the detrimental impact on CHD of social isolation in human beings.

Epidemiological studies have linked depression to CHD, and it is well known that women suffer from a higher incidence of depression than men. The role of depression in the coronary artery atherosclerosis of female monkeys has not been systematically evaluated, in part because primate depression usually has been studied with respect to developmental abnormalities caused by early separation of infants from their mothers. Recently, however, it has been shown that a proportion of socially housed, premenopausal cynomolgus monkeys exhibited behavioral and physiological characteristics that model adult human depression. This model offers for the first time the possibility of determining experimentally whether depression is causally associated with the development of atherosclerosis, the primary underlying cause of CHD.

Behaviorally Induced Abnormalities in Vascular Reactivity

Evaluation of Abnormalities in Vascular Reactivity

Numerous investigators have proposed that behavioral stress contributes to the occurrence of myocardial ischemia by causing the arteries to constrict inappropriately, thus cutting off the flow of blood to the heart. The potential for ischemia is evaluated by assessing the responses of coronary arteries to the infusion of vasoactive substances in the context of behavioral investigations. The normal endothelium, for example, dilates in response to acetylcholine. In contrast, endothelial damage causes a paradoxical constriction in response to acetylcholine. Nitroglycerine, an endothelium-independent dilator, reliably causes arterial dilation irrespective of the condition of the endothelium. Using such vasoactive substances and appropriate imaging techniques, it is now possible to visualize and quantitate the responsiveness of the coronary arteries of monkeys exposed to various kinds of stress. Such functional assessments have markedly extended the usefulness of monkeys in cardiovascular research.

Studies in Male Monkeys

In one such study, quantitative coronary angiography was used to evaluate arterial responses to acetylcholine and nitroglycerine in male cynomolgus monkeys that either were or were not exposed to the stress of repeated reorganization of social-group membership (i.e., social instability). The coronary arteries of animals living in unstable groups constricted in response

to acetylcholine, whereas those of monkeys from stable groups dilated. Significantly, the degree of constriction observed in this experiment was independent of the extent of the underlying atherosclerosis; animals with little atherosclerosis but living in unstable groups had a degree of constriction equivalent to unstable monkeys that had extensive atherosclerosis. In contrast, monkeys living in stable groups dilated, irrespective of the amount of atherosclerosis.

The previous study, and others like it, demonstrate that chronic social stress impairs endothelium-dependent vascular responses, an effect that is not necessarily dependent on the extent of atherosclerosis. It should be noted that none of these investigations revealed an influence of dominance status on vascular reactivity. Hence, the pattern of behavioral influences on blood flow (and thus on ischemia) differs somewhat from that observed with respect to atherosclerosis, at least among socially housed cynomolgus males.

Studies in Female Monkeys

As with atherosclerosis, behavioral influences on vascular reactivity among females are apparently mediated by social subordination and ovarian dysfunction. Hence, the coronary arteries of socially subordinate female cynomolgus monkeys, compared to dominants, constrict in response to acetylcholine. In contrast, nitroglycerine dilates the arteries of all monkeys, irrespective of status. As in the other studies, subordinates here were characterized by ovarian dysfunction (low plasma estradiol and luteal-phase abnormalities in progesterone). Notably, the extent of vascular constriction in response to acetylcholine was directly related to the degree of ovarian impairment as indicated by plasma estradiol concentrations on the day of testing. These observations not only demonstrate the role of behavioral factors on coronary vascular reactivity among females, they emphasize again the cardioprotective significance of normal ovarian function.

Summary

Systematic studies in nonhuman primates have shown that stress, both social and nonsocial, consistently affects the risk factors for CHD and the underlying atherosclerosis. Studies involving socially housed individuals are probably of most relevance to human beings; such investigations have focused primarily on the development of coronary artery atherosclerosis in macaque monkeys. Stress clearly exacerbates atherosclerosis in these animals, albeit differently in males and females.

Among males, dominant individuals in unstable settings and those who exhibit exaggerated heart rate reactivity to challenge are at greatest risk. These outcomes are most likely mediated by excessive SNS activation. These findings are reminiscent of observations in men linking excessive hostility and high heart rate reactivity to increased CHD risk. The monkey results imply that the pathogenicity of hostility (approximated in the animals by social dominance) is most prominent under stressful disrupted social conditions. Notably, indices of social support have not been found to predict patterns of atherosclerosis among male monkeys.

The situation among females is different. Normal ovarian function seems critical for the premenopausal inhibition of atherosclerosis among animals consuming a diet relatively high in fat and cholesterol. Notably, among groups of females, animals occupying the lower status positions are stressed and experience ovarian impairment and relative estrogen deficiency. Such individuals are characterized by a rapid acceleration of premenopausal atherosclerosis, which can be inhibited by exogenous estrogen. A novel observation is that the atherosclerosis trajectory established by premenopausal behavioral and hormonal conditions predicts the postmenopausal atherosclerosis extent. These findings suggest that primary prevention of CHD in women should begin prior to or immediately at menopause. The studies in female monkeys also identify social isolation and social support as potential factors affecting disease risk. Systematic studies of the role played by depression in the development of atherosclerosis have not yet been conducted, but they hold promise for the future.

Social Psychological Sources of Stress
Psychobiological Consequences of Stress
Environmental and Genetic Risk Factors

Glossary

<i>Model</i>	Simplified experimental system used as a testing device.
<i>Primates</i>	Mammalian vertebrates with prehensile hands.
<i>Social psychobiology</i>	The study of relationships between social, psychological, and biological processes.

Practical limitations and ethical concerns restrict opportunities for prospective controlled studies of stress in healthy humans and patient populations. Animal models that use rodents are limited because corticolimbic brain substrates of social, emotional, and cognitive control of behavior differ significantly in rats and mice compared to humans and nonhuman primates. Studies of monkeys, baboons, and apes have clearly advanced our understanding of the social psychological sources of stress, psychobiological consequences of stress, and individual differences in vulnerability and resilience related to environmental and genetic risk factors.

Social Psychological Sources of Stress

Models of stress in rats and mice often rely on exposure to cold, electric shock, or physical restraint, whereas primate models highlight the significance of seemingly subtle sources of social psychological stress.

Maternal Separation and Loss

Primate infants generally respond to maternal separation with increased secretion of hypothalamic-pituitary-adrenal axis stress hormones. The hypothalamic release of corticotropin releasing hormone (CRH) stimulates pituitary secretion of adrenocorticotrophic hormone (ACTH), which triggers the secretion of glucocorticoids (i.e., cortisol) from the adrenal cortex. An informative exception to the rule

that maternal separation elicits a robust stress response is found in one of the few primate species in which fathers provide parental care. In titi monkeys, maternal separation does not elicit an adrenocortical stress response unless the father is also removed from the developing infant. Separation from the father invariably elicits a robust adrenocortical stress response even when infant titi monkeys are left in the company of their mother. These findings concur with behavioral evidence that fathers are the primary attachment figure for titi monkey infants.

Relationship Formation and Social Reunions

Among adult primates, the formation of new relationships is often stressful, as demonstrated by measures of social behavior, elevated plasma levels of cortisol, and evidence of impaired immunity. Even reunions with well-known relatives may elicit surprising effects. When previously separated adolescent mangabey monkeys are returned to their natal social group, these monkeys and their mothers engage in frequent affiliative behavior. Nevertheless, these reunions evoke in adolescent offspring increased plasma levels of cortisol and diminished cell-mediated immunity.

Crowding

High-density living conditions are especially stressful for certain individuals, as illustrated in rhesus macaques. A statistically significant interaction between crowding and behavioral inhibition (i.e., shyness) was found to predict individual differences in the incidence of physical injury. Compared to uninhibited individuals, highly inhibited cage-mates experienced higher rates of injury during (but not before or after) crowding in the presence of ample food. Evidently, inhibited rhesus macaques are targeted for violence in high-density conditions by uninhibited peers.

Competitive Conflicts and Foraging Demands

Stressful competitive conflicts occur during foraging and feeding in primates. Even in species in which overt aggression is uncommon, there is a general tendency toward mutual avoidance during foraging and feeding. Mutual avoidance minimizes fighting when food sources are dispersed, but when food is confined to limited locations stressful conflicts often emerge. Foraging demands likewise affect maternal behavior in vervet monkeys, squirrel monkeys, baboons, and macaques. Mother-reared bonnet macaque monkeys exposed as infants to stressful foraging demands

show increased emotional reactivity when challenged later in life by maternal separation or acute exposure to novelty. As adults, these bonnet macaque monkeys are also less social, more subordinate, and present with increased cerebrospinal fluid CRH levels.

Dominance Hierarchies and Social Conflicts

Primates that live in large groups can generally be ranked within a pecking order or social dominance hierarchy. The stressful aspects of hierarchies in primate societies are not necessarily related to a particular rank *per se*, but may reflect the style by which rank is expressed and the overall context in which social hierarchies emerge. In stable hierarchies, high-ranking primates tend to exhibit metabolic, immune, and cardiovascular profiles that appear to be less pathogenic than those that are seen in low-ranking subordinates. These rank-related differences are diminished during periods of recurring conflict and social instability. High-ranking primates in stable hierarchies also tend to have lower plasma levels of cortisol, but the levels maintained in dominant baboons that lack rudimentary social skills are as high as those in subordinates.

Psychobiological Consequences of Stress

Various psychobiological consequences of stress have been characterized in primate models at multiple levels of analysis.

Hippocampal Neuropathology

Cellular and molecular markers of hippocampal neuropathology have been identified in adult monkeys following exposure to chronic stress. Similar neuropathological damage is induced when sustained-release cortisol pellets are implanted in the hippocampus. Stress-induced reductions in glucocorticoid receptor binding sites within the hippocampus impair negative feedback sensitivity on dexamethasone suppression tests in cynomolgus macaques. Recent findings in New and Old World primates indicate that the hippocampal dentate gyrus continues to generate new neurons throughout adulthood and that neurogenesis is suppressed by exposure to psychosocial stress.

Neurochemistry and Cognitive Control

Squirrel monkeys that respond to social separation with greater increases in cortisol exhibit greater increases in cerebrospinal fluid levels of the dopamine metabolite homovanillic acid. Stress increases prefrontal dopamine release, and drugs that block dopamine receptors ameliorate stress-induced prefrontal dependent cognitive deficits in rhesus macaques. Stress also decreases serotonin in prefrontal brain

regions and reduces cerebrospinal fluid levels of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA). Low levels of cerebrospinal fluid 5-HIAA are associated with a higher incidence of impulsive risk-taking behavior and excessive consumption of alcohol in adolescent macaques.

Reproductive Biology
